At the beginning, nothing is seen in daylight, and it is only in a dark room that one perceives a feeble violet glow, similar, in its intensity, to that which the discharge develops generally in gaseous systems. At the end of an hour, when in a dark room, a green glimmer is seen, which occupies the middle of the interval between the spirals of the platinum band wound round the discharge tube, the luminous spectrum gives two yellow lines at λ 579 and 577, a green line at λ 546, and a green band at λ 516·5. These different lines will be defined by-and-by.

The photographic spectrum, taken during this time, with an hour's exposure, shows the principal bands of nitrogen, as well as a blue line λ 436, a violet line λ 405, and an ultra-violet line λ 354: these latter being more feeble than the bands of nitrogen.

During the following hours, the green glow constantly increases, the yellow lines and line λ 546 increase, and the band λ 516·5 diminishes. At the end of eight hours, the bands of nitrogen have almost entirely disappeared in the photograph: without doubt it is because the corresponding nitrogen has been absorbed by the benzene.

Seven additional hours of sparking bring the fluorescence to a brilliant emerald colour, visible in broad daylight; the intensity of this phenomenon, as I have already had occasion to say,

[1] Translated from *Comptes rendus*, June 24, pp. 1386-1390.

not to be compared with the fluorescence developed by the discharge in any known gas. The yellow and green lines can be seen and measured in the spectroscope in full daylight.

The photographs give the following lines wave-lengths, λ λ 579, 577 and 540; 436, 405, 354, 313 and 312 (ultra-violet): one can see two violet lines besides, 420 and 416, scarcely visible, and the lines 385 and 358.

The spectrum observed at the end of fifteen hours was maintained during thirty consecutive hours.

Although advantage has been taken of photography for the registration of these phenomena, care must be taken not to confound such effects, observed in the daytime and under normal pressure, with the glows developed by the discharge in very rarefied gases, such as are generally observed in a spectroscope.

The meaning of these lines is as follows:

The line λ 579 is simply one of the lines visible in daylight, and under normal pressure, which I had described in *Comptes rendus* (t. cxx. p. 800), pointing out that it was probably double. The lines λ λ 580·1 and 577·1 described in the spectrum of rarefied argon, by Mr. Crookes (Jan. 24, 1895), must be compared with them.

Line λ 540 is also described (547) in my preceding note, and answers to a strong line 545·0 attributed to the spectrum of rarefied argon by Mr. Crookes. M. Deslandres has recognised the same lines in the spectrum of rarefied argon, which he had prepared by means of lithium. I have verified, by juxtaposition, the coincidence of the last line of rarefied argon with that of my tube.

I have also announced line 436, found again in the photograph, and very close to 434·5 of rarefied argon (Crookes). The lines 420 and 416 coincide with the very strong lines 420·1—416·8 and 415·00 of rarefied argon (Crookes). The line 405 can be identified with the line 404·4 of Crookes (argon). I have verified the coincidence. Line 385 coincides with Crookes' strong line 385·15 (argon). Line 354, with a group of strong lines at 354·7—353·4 of argon (Crookes). Line 358 with Crookes' group of strong lines 358·7—357·5 (argon).

λ 516·5 is a hydrocarbon band; 313 and 312 are the lines of the vapour of mercury vapour.

None of these lines, as I have already stated, coincide either with the line of helium (587·5) or with the principal line of the aurora borealis (557), although the latter is very near to a strong line of argon (555·7). If the actual fluorescence is not the same as that of the aurora borealis, still its development, and the nearness of the preceding lines, establish a probable relation between this meteor and the existence of argon in the atmosphere.

Here a very important circumstance presents itself. While examining the table of argon lines, given by Mr. Crookes, certain lines were seen to coincide with certain lines of the vapour of mercury. The same coincidence is found in the straight lines visible in daylight, under the normal pressure, in the fluorescence developed during the reaction of benzene on argon. Such are, according to M. Deslandres, the yellow lines 579 and 577; also the very characteristic green line 546, the blue line 436, the violet line 405, the ultra-violet line 354. On the contrary, the lines 420, 416, 385, 358, belong to argon only, the lines 313 and 312 to mercury.

M. Deslandres attributes the common lines to the presence of the vapour of mercury, either in rarefied argon, or in the fluorescent light obtained with benzene under normal pressure.

Nevertheless, as no known gas gives this fluorescence, or these lines, under normal pressure in operating with mercury, it is not possible to explain their production merely by the presence of the vapour alone. Otherwise it would not be understood why they did not show themselves in pure argon, in the presence of mercury under normal pressure, and that they would not produce themselves during the first moments of discharge, either with argon saturated with benzene, or with sulphide of carbon over mercury, or with nitrogen under the same conditions, where it combines with benzene and sulphide of carbon. On the contrary, with argon saturated with benzene, they develop themselves only at the end of several hours, and after the progressive transformation of the benzene into a series of compounds more and more condensed. It is one of these compounds which, immediately it is formed, unites itself both with argon and mercury, [illegible] perhaps by reason of their common character of monatomic molecules. The fluorescence begins when there still exists a notable quantity of liquid benzene in the tubes; it is then accompanied by a diminution of gaseous volume.

This fluorescence continues a very long time, even after there is no apparent benzene; at last the fluorescence ceases to be visible in the daylight, in consequence of the very prolonged action of the discharge, which at last extinguishes the green tint, and brings back this gaseous system to a glow analogous to that of ordinary gases, this happens doubtless in consequence of the destruction of the last traces of benzene (or the products of intermediate condensation), which maintained the equilibrium of the dissociation of the system.

Once the green fluorescence is well established, the compounds which develop it are stable by themselves; even after twelve hours' break, if the apparatus has not been disturbed, it suffices to pass the discharge, to see that the fluorescence re-establishes itself with all its brilliancy in an instant. But it ceases so soon as the electric current is stopped.

But if the gas is separated from the condensed matter, the phenomenon cannot be immediately produced, either on the one or on the other. The gas alone, subjected to the action of the discharge, puts on almost immediately a special violet fluorescence, visible in darkness, and which generally precedes the development of the beautiful green fluorescence. Nevertheless this does not reproduce itself then, which seems to indicate that the condensed matter contains one of the products necessary to the equilibrium. If, on the other hand, new argon is reintroduced into the tube containing the condensed matter (free from visible benzene), the green fluorescence does not reproduce itself: but after some time, near the surface of the mercury, there appears, where the sparking is most intense, a local green tint, which gives the special lines, although not very distinctly. This appearance is doubtless due to the existence (or to the regeneration) of a trace of benzene, more or less modified. In fact, if a few more drops of liquid benzene are added in the tube which contains the condensed matter and the new argon over mercury, half an hour is enough to make the green tint reappear in all its brilliancy. But if there is an excess of benzene, several hours are required for its reappearance.

These various observations, added to the limited character of the absorption of argon, demonstrate the existence of a complex state of equilibrium, in which at the same time argon, mercury, and the elements of benzene, or rather a compound condensed from it, are concerned.

THE REFORM OF OUR WEIGHTS AND MEASURES.

THE Report of the Select Committee appointed to inquire whether any, and what, changes in the present system of weights and measures should be adopted, has been published as a Parliamentary paper.

Evidence from witnesses representing official, commercial, manufacturing, trade, educational, and professional interests was received by the Committee, and numerous corporations, School Boards, and other public bodies sent resolutions in favour of the adoption of the metrical system.

All the witnesses expressed a strong opinion as to the complicated and unsatisfactory condition of the present weights and measures in use, and of the distinct and serious drawback to British commerce, especially in the foreign trade, which this system entails, differing as it does from the system (metrical) now adopted by almost every European nation, as well as by far the majority of non-European countries with which this kingdom trades. The evidence also showed that the home trade would be benefited if more simple and uniform standards of weights and measures than those now existing were adopted.

Moreover, strong evidence was brought forward as to the serious loss of time incurred by English school-children in having to learn the complicated system of tables of existing weights and measures, and the urgent need of the adoption of a simpler system. It was stated that no less than one year's school time would be saved if the metrical system were taught in place of that now in use.

Evidence from competent witnesses proved to the satisfaction of the Committee that a compulsory change from an old and complicated system to the metrical had taken place in Germany, Norway and Sweden, Switzerland, Italy, and many other European countries without serious opposition or inconvenience: that this change was carried out in a comparatively short period: and that as soon as the simple character of the new system was understood it was appreciated by all classes of the population.

and no attempt to use the old units or to return to the old system was made.

In the United States, where a system founded on the English units exists, a Commission is at present engaged in an investigation of the same character as that with which the Committee was charged, and the Federal Government has this year passed an Act rendering the metrical system compulsory for pharmaceutical purposes.

The Committee believes that the adoption of the metrical system by England would greatly tend to render that system universal.

It is recommended :—

(*a*) That the metrical system of weights and measures be at once legalised for all purposes.

(*b*) That after a lapse of two years the metrical system be rendered compulsory by Act of Parliament.

(*c*) That the metrical system of weights and measures be taught in all public elementary schools as a necessary and integral part of arithmetic, and that decimals be introduced at an earlier period of the school curriculum than is the case at present.

SCIENCE IN THE MAGAZINES.

THIS month's *Contemporary Review* is remarkably rich in articles of scientific interest. Mr. Herbert Spencer's third paper on professional institutions deals with the "Dancer and Musician." So far back as 1857, Mr. Spencer showed that, excluding movements which are reflex and involuntary, muscular movements in general are originated by feelings in general. "As a consequence of this psycho-physical law, the violent muscular motions of the limbs which cause bounds and gesticulations, as well as those strong contractions of the pectoral and vocal muscles which produce shouting and laughter, become the natural language of great pleasure." From the ways in which children manifest their joy were evolved the expressions of elated feeling with which peoples meet their conquering chief or king, and eventually the natural displays of joy came "to be observances used on all public occasions as demonstrations of allegiance, while, simultaneously, the irregular jumpings and gesticulations with unrhythmical shouts and cries, at first arising without concert, gradually by repetition became regularised into the measured movements we know as dances, and into the organised utterances constituting songs. Once more, it is easy to see that out of the groups of subjects thus led into irregular ovations, and by-and-by into regular laudatory receptions, there will eventually arise some who, distinguished by their skill, are set apart as dancers and singers, and presently acquire the professional character." In support of this interpretation evidence obtained from many nations is adduced, and the separation and secularisation of the twin professions of dancing and music are traced. Mr. G. F. Scott-Elliot writes in the same review on "The Best Route to Uganda." He is in favour of a route following the line of the African lakes. The route enters the Zambesi at Chinde, and continues up the Zambesi and Lower Shiré as far as Chiromo, from whence a railway of approximately 120 miles would be required across the Shiré Highlands to Matope, from which point the Upper Shiré is navigable, and goods can be carried to the north end of Lake Nyassa. Here another railway would be required from Karonga to South Tanganika (240 miles). From the north end of Tanganika a line would run to Kagera. The Kagera river rises on the easterly flanks of the mountains to the east of Tanganika, and eventually falls into the Victoria Nyanza. A cataract is said to exist on the river, but even if this is so, and a length of line is required to avoid it, the cost of the whole line would only be about £1,700,000, or one-half that necessary for the Mombasa railway. Other considerations point clearly to the Lake route as the better of the two suggested lines. Prof. Lombroso contributes a paper on "Atavism and Evolution." He gives a number of instances of what he regards as atavistic phenomena in social life. "England," he says, "has succeeded in establishing a form of monarchy the most liberal in Europe ; and is working out without disturbance the aims of Socialism. But, at the same time, she not only maintains the privileges of her Peers, but actually dresses them up, as well as her judges, in the wigs and robes of the Normans ; and still uses, on ceremonial occasions, the language of her ancient conquerors. . . . Then this very positive and practical nation insists on retaining a system of weights, measures, and coins, which is opposed to that of all modern Europe, and is an obstacle both to commercial exchange and to scientific research." He classifies recent inventions which are shown to be old as evidence of atavism, and explains the duplication by the dislike with which, according to him, human nature regards novelties. Too rapid advance in the arts provokes reaction and causes the tide of progress to ebb when it should be flowing. A sensible article on the "Physiology of Recreation" is contributed by Mr. Charles Roberts, in the course of which he gives the following classification of physical recreations according to their physiological value. Outdoor: running, athletics, games, skating, skipping, &c. ; riding, rowing, swimming, walking, cycling, marching. Indoor: fencing and other military exercises with arms, boxing and wrestling, dancing, billiards, dumb-bells, machine gymnastics, trapeze and high gymnastics, singing and reading aloud, playing musical instruments. Recreations of a leisurely sort, physiologically considered, are: Outdoor: natural history, gardening and farming, carpentry and other technical work. Indoor: reading ; chess, draughts, and cards ; music. Another paper in the *Contemporary*, entitled "The Origin of Man and the Religious Sentiment," by A. Fogazzaro, invites criticism from the standpoint of evolution.

Prof. Case, Professor of Moral and Metaphysical Philosophy in Oxford University, champions the cause "Against Oxford Degrees for Women," in the *Fortnightly*. He holds that the admission of women to University examinations has brought out the difficulties of teaching mixed classes, and that a mixed University is not desirable, especially at Oxford. Let women have facilities for higher education, by all means, thinks Prof. Case, but let these opportunities be afforded by a University especially founded for women. Mr. Grant Allen writes on "The Mystery of Birth," in the same review, the object of his article being to raise the question, "Is there any real and essential difference between the transmission of functionally-acquired modifications to offspring, and their registration or persistence in the individual organism?" Disciples of Weismann, and biologists generally, will be interested to know that Mr. Allen proposes "to throw back upon assimilation, in its widest sense, the burden of the mystery hitherto attached to the reproductive function."

The *Reliquary and Illustrated Archæologist* has among its articles one by Mr. H. W. Young, on the discovery of an ancient burial-place and a symbol-bearing slab at Easterton of Roseisle. A large number of flint instruments, such as arrow-heads, axes, scrapers, &c., found associated with the remains, make the discovery interesting and important, especially in relation to the geology of the "Laich of Moray."

Natural science predominates in *Science Progress* this month. The pathological results of the Royal Commission on Tuberculosis are discussed by Dr. Sidney Martin, and Mr. Arthur Keith uses Dr. Dubois' *Pithecanthropus Erectus* as a text for a helpful review of human fossil remains. The geology of the Sahara forms the subject of a paper by Mr. Philip Lake. As in July 1894, Mr. Chree shows, in an extremely valuable table, the recent values of the magnetic elements at the principal magnetic observatories of the world. In an article entitled "A Type of Palæozoic Plants," Mr. A. C. Seward directs attention to the histological structure and affinities of the genus *Calamites*, and finally Dr. W. D. Halliburton describes the formation of lymph.

Among the articles in *Knowledge*, we notice "The Sugar Cane," by Mr. C. A. Barber ; "Scorpions and their Antiquity," by Mr. Lydekker, illustrated by two fine pictures of the giant sand-scorpion of Namaqualand, reproduced from photographs, and "The Great Nubecula," by Mr. E. W. Maunder. There are also articles on the field of diameter of the field of view of a telescope, Dr. Roberts' photographs of star-clusters and nebulæ, the cause of earthquakes, and on Prof. Fraser's experiments to find a cure for snake-bites.

Blackwood's Magazine contains a paper in which Colonel Knollys dwells upon public school and Army competitive examinations. He holds that the imperfections of the training at our public schools, and the character of some of the examination papers, are responsible for the cramming now so common with candidates for the Army. Two other articles, in which our readers may be interested, are "Mountaineering Memories," by Mr. H. Preston Thomas, and "The Territorial Waters and Sea Fisheries."

A passing notice must suffice for the remaining articles of scientific interest in the magazines and reviews received by us. The *Century* has an article on "Picturing the Planets," by Prof. J. E. Keeler ; the article is illustrated by views of Jupiter,

Mars, and Saturn, obtained at the Lick Observatory. To the *English Illustrated*, Mr. Grant Allen contributes another "Moorland Idyll": and the inhabitants of "The Monkey House in the Zoo" are described and illustrated by Mr. F. Miller. In the *Humanitarian*, Mr. J. G. Raupert has a pseudo-scientific article upon "Some Results of Modern Psychical Research": and in *Chambers's Journal*, there are articles worth reading on death from snake-bite in India, the Carstairs Electric Light Railway, and citric acid. Geographers will be interested in a paper on "England and France in the Nile Valley," contributed by Captain F. D. Lugard to the *National*. Here we may also mention that the *Geographical Journal* contains a valuable paper in which Dr. H. R. Mill describes his bathymetrical survey of the English lakes. *Good Words* has an illustrated article upon the manufacture of coal-gas, but neither *Scribner* nor the *Sunday Magazine* have articles calling for comment in these columns.

THE RELATION OF BIOLOGY TO GEOLOGICAL INVESTIGATION [1]

I.

The Character and Origin of Fossil Remains.

In prosecuting the study of the fossil remains of animals and plants, the investigator may have either one or the other of its two leading objects in view; but each being so closely related to the other, it is always essential that they should be pursued with direct relation to each other. In the first case, the leading object to be attained is the extension of our knowledge of the animal and vegetable kingdoms far beyond that which may be acquired by the study of living animals and plants; and in the second case, it is to apply that knowledge to the study of structural and systematic geology. The object in the first case is purely palæontological; in the second, it is not only to acquire palæontological knowledge, but to apply it to various branches of geological investigation.

There are seven different natural conditions in which fossil remains are recognisable, three of which relate to substance, three to form, and one to both. To those relating to substance the terms permineralisation, histometabasis, and carbonisation are here applied; to those relating to form, the terms moulds, imprints, and casts; and to the one relating to both form and substance, the term pseudomorphism.

The term permineralisation applies to that condition of fossil remains of animals which differs least from their original condition as parts of living animals; such, for example, as bones of vertebrates, shells of molluscs, tests of crustaceans, &c. The term histometabasis is applied to that condition of fossilisation in which an entire exchange of the original substance for another has occurred in such a manner as to retain or reproduce the minute and even the microscopic texture of the original. Pseudomorphism of fossils is so nearly like that of mineral crystals, that this term is equally applicable to both. It consists in the replacement of the original substance of the fossil by a crystallisable or crystallised mineral, such, for example, as calcite, pyrite, quartz in the form of chalcedony, &c., the original form of the fossil being perfectly retained. The term carbonisation is applied in this connection only or mainly to such masses of vegetable remains as coal, lignite, and peat. Moulds are cavities in sedimentary rocks which were originally occupied by fossils, the latter having been subsequently removed by the percolation of water containing a solvent of the fossils but not of the rock. Imprints do not differ materially in character from moulds, the former term being usually applied to impressions left in the rock by thin substances like leaves of plants, wings of insects, &c., after their removal by decomposition. Sometimes, however, the moulds of shells and other fossils have been reduced to the character of imprints by the extreme pressure to which the strata containing them have been subjected. Casts are counterparts of fossils, having been produced by the filling of moulds with a substance other than that of the original fossil. These are the principal conditions in which fossils occur, or by which they are represented, but one occasionally finds specimens which indicate certain conditions that are not fully recognised in the foregoing descriptions.

[1] [illegible] (Abstract of a series of eight [illegible] published in the Report [illegible] United States National Museum.)

Sedimentary Formations, their Character and Limitation.

There has been much difference of custom among geologists as regards the use of the term formation, some applying it to the smallest assemblages of strata which possess common characteristics, while others designate by the same term those series of formations for which the word system has been generally used. That is, some apply the term formation to local or limited developments of strata, while others apply it to such systems as the Devonian, Carboniferous, Cretaceous, &c. This term has generally been confined to the stratified rocks, but by a few authors it has been applied to the eruptive, and also to the great crystalline, rock masses. In this paper, however, the use of the term formation is not only confined to the stratified rocks, but it is restricted to those assemblages of strata which have common distinguishing characteristics, whether they have little or great geographical extent, or whether they aggregate a few feet or thousands of feet in thickness. That is, the use of the term is confined to those assemblages of stratified rocks of sedimentary origin[1] to which many authors have applied the term group, and others the term terrane.

The foregoing remarks concerning the characterisation of formations have been made with special reference to those which are more or less fossiliferous. It sometimes happens, however, that fossils do not exist, or are not discovered, in certain formations which are evidently of sedimentary origin. This may have been due in some cases to the uncongeniality, as a faunal habitat, of the waters in which the formation was deposited, and in others to their failure to receive any fossilisable remains of animals and plants from the land. In other cases, the absence of fossils may have been due to their destruction or obliteration. The latter has probably been the case with many metamorphic rocks and with the great pre-Cambrian series of stratified rocks generally. In all these cases the formations, while they may possess more or less distinct physical characteristics, lack the chief characteristics of sedimentary formations, namely, the biological.

The occurrence of an unfossiliferous sedimentary formation as a member of an otherwise fossiliferous series is unusual, but in such a case its definition and limitation would be effectually accomplished by the underlying and overlying formations. In the case, however of a great unfossiliferous series of stratified rocks like the pre-Cambrian it is necessary to adopt a method for their study and classification based wholly upon physical data, after the fact that they are pre-Cambrian has been determined from biological data. Such a method of classifying and characterising those unfossiliferous stratified rocks as they occur in North America has been proposed by Prof. R. D. Irving[2] and afterwards elaborated by others. This great series of rocks, as it is developed in America, has such distinguishing general characteristics and such magnitude and geographical extent, that some geologists have thought it worthy of being assigned to a special division of study, but because no certain traces of organic forms have been discovered in them, they have, so far as it is now known, only the indirect relation to biological geology that has just been referred to. Still it is not improbable that those strata were once fossiliferous, and that the great series was once made up of formations similar to those which have been already defined, but it does not necessarily follow that the divisions which are now recognisable by physical characteristics correspond to those formations. It is probable that they more nearly correspond to systems or to the larger divisions of systems as they are recognised in the great scale of the fossiliferous rocks of the earth.

The following conclusions concerning formations are deducible from a consideration of the available facts:—

While formations are physical objects and have only a physical existence, their proper characterisation is chiefly biological.

They are characterisable mainly by the fossil remains of aquatic faunas.

Neither their physical nor biological limits are sharply defined except as a result of accidental causes.

Their geographical limitations are indefinite except those which were occasioned by shore lines.

[1] To avoid frequent repetition, the terms sedimentary formation and stratified formation are used interchangeably when applied to formations as defined above. The terms sedimentary rocks, stratified rocks, and fossiliferous rocks are also used interchangeably, but with a somewhat more general meaning than is intended by the two former terms.

[2] Irving, R. D.: "Classification of the Early Cambrian and Pre-Cambrian Formations." (Seventh Ann. Rep. U.S. Geol. Survey, pp. 371-399.)

They do not necessarily bear any close relation to one another as to geographical area, thickness, or the duration of time in their accumulation.

Although they are thus unequal to one another, they constitute the only available physical units for local or regional stratigraphic classification.

Because of their limited geographical extent they cannot be used as units of the universal classification of the stratified rocks.

THE RELATION OF FOSSIL REMAINS TO STRUCTURAL GEOLOGY.

There are two methods by which the study of fossils may legitimately be applied to geological investigation, and the following statement of the character of these is in part explanatory of the results that may be obtained by their aid. For convenience, one of them may be termed empirical and the other philosophical, because in the one case results are obtained by experience, and in the other by reasoning upon the various results thus obtained. Still, discrimination between these two methods cannot usually be sharply drawn, because, while all geological investigation is largely empirical, it is always more or less philosphical. Such a division of the subject, however, besides being a convenience, gives an opportunity to emphasise the fact that a large proportion of the work that is done in structural geology is based mainly upon the empirical observation and collection of biological data.

Both these methods are not only important but indispensable, the one not less so than the other. Both may be, and aften are, used together, but the empirical method is more largely used in practical field studies than in others, because in such studies fossils are to a large extent treated as characteristic tokens of formations, or as arbitrary means of identifying them and distinguishing them from one another. Such identification necessarily constitutes one of the first steps in the practical study of structural geology, but the subsequent study of the fossils thus empirically used is necessarily more philosophical.

The philosophical method of treating fossil remains, however, is largely applicable to systematic geology or those branches which pertain to the universal chronological classification of the sedimentary formations and to their correlation in different parts of the world. The naturalist studies fossil remains as representatives of the long succession of progressively and differentially developed organic forms which, during geological time, have existed and become extinct, and of which succession the now existing forms of life constitute only the terminal portion. It is the results of such studies as these that the geologist uses in the philosophical studies referred to.

Of the two ways in which formations are naturally characterisable, one is physical and the other biological. Physical characterisation may be direct or general, that is, it may be by identity of kind or kinds of rock of which the formation is composed, or by its possession of that more general or indefinite property or condition which indicates homogeny.

Formations are biologically characterised only by the fossil remains of animals and plants which lived while they were in process of deposition, and the more intimate the natural relation of any of those animals and plants to the physical conditions which produced a formation, the more characteristic of it are their remains. This implies that, while no kind of fossil remains is to be rejected in practical studies of structural geology, there is much difference in the value of the different kinds for this purpose. These differences in value will be specially discussed later on.

Much has been written on methods of distinguishing between formations of marine and non-marine origin, and the legitimate inferences that may be drawn from them, respectively, as to the physical conditions which prevailed while they were accumulating. It is desirable here to present some remarks upon the relative value in practical geological field work of the fossils found in marine and non-marine formations, respectively.

That the fossil remains of marine faunas are far more valuable as indicators of the chronological divisions of the geological scale and of the correlation of its divisions in different parts of the world than are those of non-marine faunas, is apparent to every one who is familiar with even the general facts of biological geology, but it does not follow, and it is not true, that the latter are intrinsically less valuable than are the former in field studies of practical geology. For this practical work, both marine and non-marine fossils are treated by the empirical method already explained, and both are found to characterise the respective formations in the same manner.

Certain conditions, however, give each an advantage over the other under different circumstances. For example, the geographical range of the non-marine invertebrate fossil faunas, especially those of fresh water, having been sharply defined by shore lines, the species which constituted them are to that extent more characteristic of the formations in which they occur than is the case with marine faunas. Certain species of the latter faunas, as already shown, usually ranged beyond the limits of the area which was occupied by each fauna as a whole.

Non-marine formations, as a rule, occur singly in a series of marine formations, in which case the vertical as well as the geographical range of their invertebrate species is sharply defined. It is true that in the interior portion of North America there is a continuous series of fresh-water formations, and that certain of the species range from one into another. These, however, are notable exceptions to the rule referred to, and they at most only make such non-marine faunas equal to the average marine fauna as regards exceptional vertical range of species. Again, non-marine formations usually have the advantage of the presence of remains of plants and of land vertebrates and invertebrates, which in marine formations are usually so extremely rare as to be unavailable.

On the other hand, marine faunas embrace such a wide diversity of forms as compared with the non-marine, and their progressive and differential evolution from epoch to epoch has been so much greater, that they offer as faunas much more abundant means for the characterisation and identification of formations. It is clear, however, that the opinion which some geologists have expressed or implied, that the fossil contents of non-marine formations are of little value in practical geological investigation, is not well founded. The following conclusions sum up the case :

Formations being the only true units of local or regional stratigraphic classification, their correct identification is the first, and an indispensable, step in the practical field work of structural geology.

Although formations as such have only a physical existence, their biological characteristics are always the best, and often the only, means of their identification, and therefore the exhaustive study of fossils is of paramount importance in connection with all practical investigations of that kind.

The value of fossils in this respect is as purely practical as is that of any other aid to geological investigation, and it may be made available without reference to their great value in other respects.

Although all fossil remains are valuable for this practical use, those of aquatic faunas are more valuable than any others.

Remains of non-marine faunas are of similar value for this purpose to those of marine origin.

THE RELATION OF BIOLOGY TO SYSTEMATIC AND HISTORICAL GEOLOGY.

It has been made apparent in the preceding sections that each case of structural classification of stratified rocks based upon formations as physical units is independent of all others, and that its application is necessarily of limited geographical extent, because formations are themselves thus limited. It therefore follows that the structural geology of any district or region, embracing even an extensive series of formations, may be practically and thoroughly investigated, as regards both scientific accuracy and economic requirements, independently of that of any other district or region, especially of those regions which are not adjacent. It is now to be shown how the multitude of series of formations thus locally classified throughout the world have been grouped into a universal system of classification in connection with a scale having its divisions arranged in chronological order.

When the fossil faunas and floras which characterise each of a given series of sedimentary formations are compared with those which severally characterise the formations of the next preceding and succeeding series, and the whole are systematically compared with living faunas and floras, there is to be observed among those fossil forms, when studied through an unbroken vertical range of formations, an order of successive changes and modifications indicative of a general advance in biological rank, and also an indication of structural relationship. Furthermore, when the faunas and floras of a given series of formations are compared with those of other series in other parts of the world, it frequently appears that there is a close similarity between those of a certain portion of each series which indicates their correlation. In such cases an order of biological rank is to be observed

similar to that which was observed in the original case. It also frequently occurs that the range of rank is found to be greater in one or both directions than is to be observed in other cases. By such means a knowledge of the order of faunal and floral, as well as of stratigraphical, succession far beyond that which could be obtained in any one region, has been acquired.

It is upon such empirical facts as these that the early geologists based their investigations concerning the chronological arrangement of the sedimentary formations of the earth, and the grand result of which was the adoption of a general scheme and the construction of a corresponding scale for their classification. This scale, which in its present condition is a masterpiece of inductive reasoning, necessarily originated in Europe, because it was there that geology was first systematically studied, and it is there also that its adaptation is more complete than elsewhere.

Although the scale now in use was established before the truth of the progressive evolution of organic forms was accepted by naturalists, and when all differences between those forms was believed to be due to special creations, general progression in average biological rank during geological time was perceived by the early geologists, as well as by those of the present day; but with them it was the perception of a progressive succession in rank of faunal and floral groups of great assemblages of organic forms, and not the recognition of the principle of evolution. Therefore they sought methods of explaining the facts and conditions which they observed with reference to the geological scale which they had established that should accord with the theological views which then prevailed, and which were largely of a supernatural character. Indeed, in the absence of the now prevalent natural method of explaining these facts, the supernatural method of the early geologists seems to have been necessary.

The following deductive propositions which now remind a naturalist of the articles of a creed more than of a statement of scientific principles, are presented as indicating the fundamental ideas held by the early geologists in connection with the construction of the geological scale, and as illustrating the state of prevalent opinion among leading geologists upon biological subjects in their time. It is true that no one author has ever published these propositions in the exact form in which they are here presented, but they have been formulated from the published utterances of numerous authors, and from personal recollections of an active participation in geological work during a number of years, immediately preceding the great revolution in methods of biological thought and investigation which has been referred to. These propositions are:—

(1) That every species of animals and plants, both living and extinct, was specially created, and that they are, and always have been immutable. That genera, and also the higher groups into which both the animal and vegetable kingdoms are systematically divisible, are categories of creative thought, and that they also are immutable.

(2) That although secular extinction of certain species, and [illegible] genera, occurred during every stage of the geological scale, at the close of each stage, except the Tertiary, all life upon the earth was simultaneously destroyed, and that at the close of each sub-stage life was at least in large part destroyed.

(3) That, at the close of each stage coincidently with, and the [illegible] ordained instrument of, the complete extinction of life, there was a universal physical catastrophe, and that the close of each sub-stage was, at least in part, physically catastrophic.

(4) That all life for each successive stage was created anew.

(5) That the life of each stage embraced specially ordained [illegible], or more general, types which were distinctive of and [illegible] to it, and that their distribution was world-wide.

(6) That there was a special ordination of characteristic types for each sub-stage, which received world-wide and simultaneous [illegible] within its narrow time limits.

(7) That no identical, and few similar, specific forms were [illegible] for any two or more stages.

(8) That the world-wide distribution of the distinctive types of animals and plants which were ordained to characterise any [illegible] was effected in connection with the act by which [illegible] faunas and floras were created; or that [illegible] having a world-wide distribution the [illegible] faunas and floras was preserved by the introduction of [illegible] that is, closely similar but distinct [illegible].

(9) That [illegible] the average biological rank of each [illegible] of the next preceding one.

(10) That upon the fossilisable parts of the animals and plants which were created for each stage, and upon those designed to characterise each sub-stage, was impressed not only their own structural features, but recognisable evidence of their chronological ordination.

These propositions represent only those views of the pioneer geologists which pertain to biological geology. Other views which were held by them are unassailable, even in the light of the present advance of science, and their biological views are not introduced here for the purpose of disparagement, but to show that they gave origin to certain erroneous methods which are in part retained as an inheritance by some palæontologists, even though they ostensibly accept the principles of modern biology.

The foregoing propositions relate to what were regarded by the early geologists as fundamental ideas in the construction of the geological scale, while the following relate to those ideas which are now held to constitute its true basis because they only accord with natural laws. These are therefore essentially a counter-statement of the preceding propositions; but the principal object of their preparation is to point out the true relation of biology to systematic, historical, and correlative geology. They consist largely of the statement of certain of the principles involved in the theory of organic evolution, but they are by no means intended as a full statement of those principles, nor are they presented for the purpose of either discussing or defining them as such. That is, the statements are made not for the purpose of formally enunciating these principles, but for the purpose of making practical application of them to the subject in hand. Such of these have been selected for statement and comment as are believed to be accepted by all naturalists who admit the truth of organic evolution, and such application is made of them as will necessarily commend itself to all geologists who admit that truth and its applicability to biological geology.

These propositions are not intended to embrace the whole range of biological geology, but only such of its leading principles as are discussed in these essays. Therefore a certain lack of immediate relevancy will appear in the order in which they are stated.

(1) All species of animals and plants have originated genetically from pre-existing forms, and therefore all are more or less mutable as regards their reproduction. These, together with the various divisions higher than species into which the animal and vegetable kingdoms are divisible, have respectively acquired their distinguishing characteristics by differential and gradually progressive evolution. The extinction of all species and other divisions of the animal and vegetable kingdoms which has taken place during geological time, has always been by natural means and in accordance with natural laws. It has generally been secular and gradual, but in many cases locally or regionally accidental. No universal extinction has ever occurred.

(2) Coincident with the progress of evolution, notwithstanding the retardation, inertion, and even degradation that have occurred along certain lines, there has been during geological time a general average advancement in biological rank of animal and vegetable forms, evidence of which is afforded by certain characteristics of their fossil remains. The evidence of this general advancement constitutes the ultimate standard of measures of geological time as a whole, and the principal means of ascertaining the order of full succession of the events which attended the production of the stratified rocks of the earth.

(3) The chronological features which fossils possess are not of a special character as such, but they are among those upon which their biological classification is based, all of which features have resulted from both progressive and differential evolution.

(4) The average rate of progressive evolution for the different branches or divisions of both the animal and vegetable kingdoms has not been the same for each in all parts of the world, nor the same for all in any one part of the world, during all the time they have coexisted.

(5) The rate of differential evolution among the forms constituting certain divisions of the animal and vegetable kingdoms was greater than that among those constituting other divisions; and it was greater for some of the members of a given division under certain conditions than it was for other members of the same division under other conditions.

(6) The succession of gradual mutations, in the development of the leading classificatory features which characterise certain groups of fossil forms, was not necessarily concurrent with consecutive portions of time.

(7) The progress of secular extinction of species and other divisions of the animal and vegetable kingdoms, including the types which specially characterise the various stages and sub-stages of the geological scale, was accelerated by adverse changes of environing conditions, and were retarded by a continuance of congenial conditions. The final consummation of the extinction of the types was naturally often, and perhaps usually, caused by catastrophic changes of conditions which occurred within the limited areas to which they were reduced by approaching secular extinction.

(8) The geographical distribution of species within the time-limits of the stages and sub-stages of the geological scale, and consequently that of the distinguishing types which the species constitute, has been effected by natural means. Such means included not only locomotory and mechanical dispersion within those time-limits from one original centre which was then the terminus of an evolutional line, but, at least in the same cases, survival in various regions by separate evolutional lines from the faunas of preceding stages and sub-stages was also included.

(9) The animal and vegetable life of each stage of the geological scale was in the aggregate different as to its forms from that of all others, and each stage and sub-stage was further specially characterised by certain generic, and also more general, types or peculiar groups of species. These types, however, were not necessarily confined within absolute time-limits.

(10) Although movements and displacements of the earth's crust have from time to time occurred over large portions of its surface, arresting sedimentation or changing its character and causing great destruction of life, there has never been a universal catastrophe of that kind. On the contrary, during all the time that disastrous conditions prevailed in any given area, conditions congenial to the existence and perpetuity of life prevailed in other and greater areas.

The second of the two sets of propositions show that certain of the views held by the early geologists, notably those which assumed the universally sharp definition of all the divisions of the geological scale, were radically wrong. Still, it is evident to every one who is familiar with modern geological literature that those views have continued to exert an adverse influence upon the biological branch of geological investigation long after they have been formally rejected, even by those who continued to be influenced by them. The early geologists adopted methods of investigation which were consistent with their biological views, but it has been shown that from the present standpoint of biology certain of those views were so fundamentally wrong that the methods which were based upon them are quite out of place in modern investigation. Still, those methods of our energetic predecessors have come down to the present time with such force and with such evidence of the general correctness of the scale which they had established by them, that it has been difficult for their successors to adopt the modification of methods which has been necessitated by the great subsequent revolution in biological thought and methods of investigation.

The facts which have been stated show that, while the scale which the early geologists established is a wonderful production of human reasoning and the best possible general standard which can be adopted before a comparatively full investigation of the geology of the whole earth has been made, it is not, and cannot be except in a general way, of universal applicability. That is, while the respective stages and sub-stages of the scale are recognisable only by means of their characteristic fossil remains, it has been shown that any of those characteristic forms are so liable to range from one stage or sub-stage to another, that it is impossible to sharply define the limits of stages, and often impossible to distinguish sub-stages in one part of the world as they are known in another part.

(*To be continued.*)

SCIENTIFIC SERIALS.

Bulletin de l'Académie des Sciences de St. Pétersbourg, V[e] série, t. ii. No. 2, February 1895.—We notice in the proceedings of the meetings, that the full account of Baron Toll's observations in the New Siberia Islands will soon be published by the Academy. In the meantime the explorer has visited Switzerland in order to study glacier ice, and has found there further proofs, supported by A. Forel, in favour of the masses of ice which he has found in New Siberia (buried under clays containing fossil stems of *Alnus fruticosa* fifteen feet long), really being remains of the ice-sheet which covered the islands during the glacial period.—The yearly report of the Academy, which contains, among other matters, the obituaries of L. Schrenck, A. Middendorff, I. Schmalhausen, and P. Tschebycheff, whom the Academy has lost during the last year.—The positions of 140 stars of the star cluster 20 Vulpeculæ, according to measurements taken from photographic plates, by A. Donner and O. Backlund (in German). The measurements were taken on two plates, one of which had been exposed for twenty minutes only, and the other for one hour, and the accord between the two is most satisfactory, the average difference being 0·00s. in right ascension, and 0"·02 in declination, while the difference between the measurements on the photographic plates, and the direct measurements of Schultz, attains on the average −0·040s. in R.A. and −0"·55 in D.—On the differential equation $dy/dx = 1 + R(x)y$, by N. Sonin.—On a new entoptric phenomenon, by S. Chirieff.—Note on the last mathematic conversation with P. L. Tschebycheff, about his rule for finding the approximate length of a cord, and the means of extending the method to curves of double flexure (all three in Russian).—The ephemeride of the planet (108) Hecuba, by A. Kondratieff.

Vol. ii. No. 3, March 1895.—Yearly reports of the Philological Section of the Academy, and of the committees: for the Baer premium, which was awarded this year to the Tomsk Professor Dogel, for his researches into the histology of the nervous system, and to Prof. Danilevsky for researches into the comparative study of parasites in blood, and the Lomonosov premium, which was awarded to A. Kaminsky for his work on the yearly march and geographical distribution of moisture in the Russian empire in 1871–90.—On the Perseids observed in Russia in 1894 (in French), by Th. Bredikhine. The observations were made by several observers at Odessa and at Kieff. It must be remarked that the observers have had difficulty in observing the meteors, the course of which made a sharp angle with the direction of the vertical line; and this circumstance is probably not without some influence upon the determination of the radiant point. The meteors observed on July 24, 26, and 27, seem to belong to a meteoric stream other than the Perseids. Combining the results of this year's observations (which are given in full in thirteen tables) with the observations of the preceding year, and calculating the elements for each of the radiants, the author sees in them a confirmation of the theoretical results he arrived at in his paper on the Perseids of 1893; the values of the inclination (i) of the centres of radiation—with the exception of the three first, which are somewhat uncertain—are all below the value of i for the comet of 1866. The average value of i before the epoch (August 10·5) is 60°, while after that time it is only 56°; but this decrease cannot be considered as quite real, on account of the said uncertainty in i for July 24–27. An inspection of the charts shows that a condensation of the radiation is taking place towards the epoch which falls on the night of the 10th to the 11th, as seen from the observations made in Italy by P. Denza. The arithmetical average of the coordinates of the three chief radiants of August 10 are $\alpha = 48° 48'$, and $\delta = 56° 30'$, we have: $l = 63° 32'$, $b = 36° 51'$, $i = 64°·8$, $s = 72°·8$, and $V = +34°·4$. The value of i corresponds to the radiant of the comet of 1866. Considerable variations appear in the elements Ω and π; the perihelium is displaced in the direction of the orbital motion of the meteors. In a subsequent memoir the author proposes to take up the theory of the subject, and to evaluate the secular variations of the generating orbit of the comet, and of some of its derived orbits.—On the best means of representing a surface of revolution on a plane, a mathematical treatment of the subject, in Russian, by A. A. Markoff.—On the limit values of integrals, by the same.—List of the works of P. L. Tschebycheff.—On the methods for correctly determining the absolute inclination by means of the induction inclinator, and the degree of exactitude lately obtained with this instrument at the Pavlovsk Observatory, by H. Wild (in French).—The non-periodical variations in the quantity of precipitation at St. Petersburg, by E. Heintz (in Russian, summary in French).—Ephemeride of the planet (209) Didon, by Mme. Eugénie Maximoff.—Determination of the magnitudes of the stars in the star cluster 20 Vulpeculæ, by Mme. Marie Shilow. The diameters were measured by the micrometer, and the corresponding magnitudes were calculated by means of Charlier's formula.—On one sum, a mathematical note (in Russian), by I. Ivanoff.

THE numbers of the *Journal of Botany* for May to July contain, besides mere technical papers, one on the genu

Argemone, by Dr. D. Prain, a description of a new species of *Bryopsis*, and of a peculiar mode of growth in another species, by Miss E. S. Barton; an account of fossil plant-remains in peat, by Mr. A. Gepp; and a description of a large number of new species of Orchidaceæ, by Mr. A. B. Rendle, from the plants brought by Mr. Scott Elliot from Tropical Africa.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 16.—"The Complete System of the Periods of a Hollow Vortex Ring." By H. C. Pocklington.

May 30.—"The Kinematics of Machines." By Prof. T. A. Hearson.

In this paper it is shown that all machine movements, however complex, are derived from the association together of some of a comparatively limited number of kinds of simple motions, which take place between consecutive directly connected pieces.

Certain geometrical laws are enunciated, from which are derived the conditions necessary for the association of those motions together in one machine. It is shown that those laws preclude the existence of certain combinations of motions. By attaching to each kind of motion a suggestive symbol a method of expressing the constitution of a machine movement by a simple formula is proposed, whereby similarities and differences between machines may be exhibited at a glance.

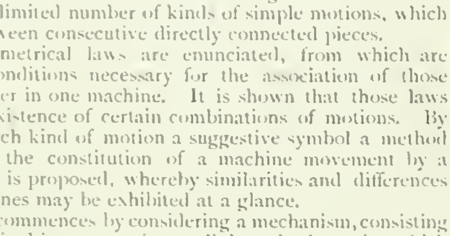
The author commences by considering a mechanism, consisting of four bars united in one continuous linkage by four pins which have parallel axes. By imagining the length of the links to undergo variation from zero to infinity, it is shown that this mechanism is representative of all the simple plane mechanisms, and, by imagining other variations to occur, it is shown to be representative of still further classes of mechanisms, in which the parts do not move in or parallel to one plane. In this the relative motions of consecutive pieces are either turning, when one piece revolves completely around relatively to the other, the representative symbol being the letter O, or swinging, when one piece turns through a limited angle relatively to the adjoining one, represented by the letter U.

O Group.

O Group.

O Group.

U Group



The first law enunciated, which governs the association of the O and U motions, is founded on the geometrical fact that the sum of the four angles of the quadrilateral is constant. After a complete revolution the angle between the bars is considered to have been increased or diminished by 2π.

From this it is impossible for only one motion to be turning and the other three swinging, otherwise the sum of the four angles would increase or decrease by 2π each revolution.

The second law, which governs the association of the motions, has to do with the proportions between the length of the links necessary to permit of complete turning. This is founded on the fact that one side of a triangle cannot be greater than the sum of the other two. From these two laws together it is shown that it is impossible to have two Os alternating with two Us.

Next it is pointed out how the U motion may be provided for by constructing a circular slotway in one piece, and shaping the other piece to fit the slotway, so that by imagining the radius of curvature of the slotway to be indefinitely increased a relative movement of reciprocating sliding motion, represented by the symbol of letter I, will be substituted for the swinging motion U. A slide being conceived to be a swing through a zero angle about an infinitely distant centre, the previously mentioned laws will apply to associations containing I motions, and it will follow that a combination of three slides and one swing is precluded by the first law.

By the application of the governing laws 14 distinct combinations are found to be possible, and only 14. They are exhibited by the following formulæ, in which a large O associated with a small o signifies that in one case adjacent links turn relatively to one another so as to continuously increase the angle between them, and in the other to continuously diminish the angle. The double ◎ signifies that two complete revolutions accompany one complete to-and-fro swing or slide.

Applying Reuleaux's principle of "Inversion" it will be seen that 32, and only 32, distinct machine movements can be derived from the above 14 mechanisms. Those from the same mechanism are distinguished from one another in the formula by using a thick line for the frame link. For example,

 signifies a machine movement like that employed in the crank-and-connecting-rod engine.

 is exemplified in the oscillating engine much used in paddle-wheel steamers.

 is found in Stannah's pendulum pump, and

 quadrupled is the movement adopted by Rigg in the design of his high speed engine.

The author next discusses the relation of cams and spur-wheel mechanisms to the foregoing kinematic chains, showing that they are the result of the suppression of one of the previous four links and the amalgamation of the two adjoining simple motions into one more complex. A comparison is also made with belt gearing, and expressive formulæ suggested.

The author then passes to the consideration of machines the parts of which do not move parallel to one plane.

The first 13 of the previously mentioned mechanisms have their counterpart in mechanisms the parts of which move parallel to the surface of a sphere. Hooke's joint is the best known example. The 14th consisting of 3 slides cannot be adapted to a sphere but it can to a cylinder, and from it are derived 4 possible screw mechanisms.

The remaining mechanisms consist of those in which the axes of the turning and swinging motions neither meet nor are parallel. They include the motion which occurs at a ball-and-socket joint. The method of classification according to the proposed scheme is summarised as follows:—

All simple machine movements may be ranged in four divisions, viz.:—

(1) Consisting of plane mechanisms, in which the pieces move in or parallel to the surface of a plane.

(2) Spherical mechanisms, in which the pieces move in or parallel to the surface of a sphere.

(3) Cylindrical mechanisms, in which the pieces move in or parallel to the surface of a cylinder.

(4) The remainder, to which the name conoidical mechanisms is given, in which the axes of the swinging and turning motions neither meet nor are parallel.

The mechanisms in each of these divisions are classed in two subdivisions.

Subdivision S, with surface contact of consecutive links.

Subdivision P, with point contact of consecutive links.

The mechanisms in each of the eight subdivisions are still further subdivided into combinations. The combinations of 1_s, 2_s, and 3_s, are exhaustively enumerated, and it is suggested that an extension of the methods of applying the geometrical laws would lead to the preparation of an exhaustive list of the possible combinations in the other subdivisions. The combinations are still further subdivided into inversions according to Reuleaux's principle of the inversion of a machine.

Lastly, the author proceeds to show how the foregoing considerations assist in the analysis of compound mechanisms. It is assumed that practically all compound mechanisms contain a continuous mechanism A, of not more than four links, from which definiteness of relative motion of all the other links is derived. Any two links of A in their exact length, or longer or shorter, may be adopted to form with two new links a second mechanism B, and any two of A or B, or one of A and one of B, may be adopted to form with two still further added links a third mechanism C, and so on. In this way a definiteness of relative motion of many links in a compound mechanism is derived. The notation lends itself to a clear exhibition of the

manner in which two or more simple mechanisms are associated together, and the compound mechanism built up.

June 20.—"The Influence of the Cerebral Cortex on the Larynx." By Dr. J. S. Risien Russell.

The author found the condition of the peripheral laryngeal apparatus has practically no effect on the result obtained from the central nervous mechanism, for abduction or adduction of the vocal cords resulted on excitation of the appropriate area of the cerebral cortex, irrespective of whether abduction or adduction was obtained on excitation of the recurrent laryngeal nerves in the same animal. No evidence of unilateral representation of the movements of the vocal cords in the cerebral cortex was obtained, although this point was tested in various ways. Nor was it found possible to inhibit the abductor muscles by excitation of the cortical centre of their antagonists the adductors. It was found that both in the dog and cat there existed a focus, excitation of which resulted in adduction of the vocal cords, and another near to this, stimulation of which resulted in abduction of the cords. While in the cat it was possible to differentiate these movements without any preliminary measures being adopted, it was only after the adductor fibres of one recurrent laryngeal nerve had been divided transversely that it first became possible to evoke abduction of the vocal cords on excitation of the cortex, though in subsequent experiments it was sometimes possible to evoke this movement on excitation of the cortex of the dog without adopting this preliminary measure. The other effect on the cords, which it was as a rule found most difficult to differentiate from that of abduction, was acceleration of their movements. It was further found that on the anterior composite gyrus, below the abductor centre, there existed a focus, excitation of which resulted in a clonic adductor effect on the cords, in which the cords were first brought into a position of moderate adduction, and then there was added rapid short to-and-fro excursions. On passing within the confines of Spencer's area for arrest of respiration, it was found that in the peripheral parts of this area there existed three foci, excitation of which affected the cords in different ways. The most anterior was responsible for arrest of the cords in adduction, *i.e.* in the expiratory stage of their excursions; excitation of the focus behind this, and corresponding, probably, to Horsley and Semon's abductor centre in the cat, was followed by arrest of the cords in abduction, *i.e.* their inspiratory position; while the most posterior focus, which is situated at about the junction of the anterior composite and anterior sylvian convolutions, resulted in intensification combined with acceleration of the movements of the cords when stimulated. Excitation of Spencer's chief focus for arrest of respiration on the olfactory lobe, resulted in arrest of the cords in the position they occupy during expiration in the dog, and in the position they occupy during inspiration in the cat.

Physical Society, June 28. Dr. Gladstone, Vice-President, in the chair.—Mr. Bowden read a note on an electro-magnetic effect. A long glass tube containing mercury, and fitted with a small stand-pipe to indicate hydrostatic pressure, is passed between the poles of an electro-magnet. On passing a current of about 30 amperes through the mercury in this tube, the stand-pipe being turned so as to indicate the pressure either perpendicular or parallel to the lines of force of the field of the electro-magnet, movements of the mercury in the stand-pipe take place. When the stand-pipe is perpendicular to the lines of force of the field, the mercury rises or falls according to the direction of the current. When the stand-pipe, however, is parallel to the lines of force, the mercury always *rises*, whatever the direction of the current. Prof. S. P. Thompson said there appeared to be three unexplained effects, one proportional to the current and the field, and reversible; another, independent of the direction of the current, or of the field; and a third, which only occurred while the current was changing in strength. In addition there may be a fourth effect, which up to now has not been noticed. The motion of the mercury column in Fig. 1 of the paper was in the opposite direction to that of the drag on a conductor carrying the current. An apparent *rise* in pressure might be due to a decrease in the density of the mercury due to the heat developed by the current. Mr. Blakesley asked if the author had noticed any changes in level in the mercury reservoirs at the ends of the tube. The author, in his reply, said the reservoirs at the ends were so large that no changes of level were appreciable. Mr. Rhodes read a paper on the armature reaction in a single phase alternating current machine. In this paper the author gives the investigations that were the subject of a verbal addendum to a paper read before the Society on a previous occasion. He investigates the lag or lead of the E.M.F.s over the current, and applies the results to examine whether the field excitation of the generator or the motor is strengthened or weakened by the reaction of the armature currents. Mr. Tunzelmann expressed a hope that the author would amplify parts of his paper. Mr. Blakesley said the conclusion of the author that "either of two alternate current machines may be driven as a motor by the other, irrespective of their relative E.M.F.s," is not invariably correct. The facts of the case were these: the E.M.F. of the motor may exceed that of the other machine to a certain extent; but that E.M.F., multiplied by the cosine of the angle of electric lag, must yield a product not greater than the E.M.F. of the generator; *i.e.* using Mr. Rhodes' symbols $e \cos \theta$ must not be greater than E. Mr. Blakesley gave a geometrical proof of this, but the same proposition had been given by him some ten years ago in the course of investigating the subject generally. This was at a time when Dr. John Hopkinson was, with less than his usual perspicuity, teaching that synchronous alternate current machines could not be run in series with stability, both doing work. Referring to the author's diagrams, Mr. Blakesley said that in a problem involving so many elements as that under consideration, it was impossible with the limited dimensions of space to represent the results with the complete generality of a formula. Some elements had to be taken as the independent, others as the dependent variables. The author had considered the power transmitted to the motor, the E.M.F. of the generator and the angle of electric lag as independent. The E.M.F. of the motor was dependent. In Mr. Blakesley's original diagrams the E.M.F.s were both considered independent as well as the electric lag, and the powers applied or transmitted as dependent variables. In any case the formulæ properly derived from such diagrams became perfectly general, and it did not appear to him that the change of method indicated could properly be called a new theory on the subject. As a matter of fact, diagrams based on the independence of the E.M.F.s and the electric lag would furnish a better means of discussing the question of the stability of the motion than Mr. Rhodes' plan, and this might account for the entire omission from the paper of this important matter. Prof. S. P. Thompson said it was impossible to discuss the question of stability till the subject of armature reaction had been thoroughly investigated. The terms lag and lead had been used by Mr. Rhodes in a consistent manner; but this was not always done, and he recommended that the phase of the current which was common to both generator and motor be taken as the standard. The author, in his reply, said he agreed with Mr. Blakesley that there was a limit to the extent to which the motor might be excited, and this upper limit could easily be obtained from the figure given in the paper. The question of armature reaction was, however, most important, as it might excite the field two or three times more than the original excitation. Since motors were designed to do a certain amount of work, and not the work to fit the motor, it was most natural to take the output of the motor as fixed. Mr. Shelford Bidwell read a paper on the electrical properties of selenium. The author has continued his investigations on this subject, and has come to the following conclusions: (1) The conductivity of crystalline Se appears to depend principally on the impurities which it contains in the form of metallic selenides. It may be that the selenides conduct electrolytically, and that the influence of light in increasing the conductivity is to be attributed to its property of facilitating the combination of Se with metals in contact with it. (2) A Se cell having platinum electrodes, and made with Se to which about 3 per cent. of cuprous selenide has been added is, even though unannealed, greatly superior both in conductivity and sensitiveness to a similar cell made with ordinary Se and annealed for several hours. (3) Red Se in contact with copper or brass, is quickly darkened by the action of light, owing, it is suggested, to the formation of a selenide. (4) Crystalline Se is porous and absorbs moisture from the air, and it is this moisture that causes the polarisation of Se after the passage of a current. (5) The presence of moisture is not essential to sensitiveness, but appears to be in a slight degree favourable to it. (6) If cuprous selenide is made the kathode in an electrolytic cell, and a strip of platinum the anode in water, red Se mixed with detached particles of the selenide is deposited in the water. (7) The photo-electric currents sometimes set up when light falls upon Se, are dependent upon the

... voltaic origin. So perfectly dry Se is below platinum in the thermo electric series. Prof. Minchin (communicated) suggested that the selenium "cell" should be called a selenium "resistance." A grid having one terminal made of aluminium and the other of copper, might form a true cell, and might generate an E.M.F. when light fell on it. He (Prof. Minchin) would like to know if the author had tried any such cell in which light simply and solely generated an E.M.F. He could not agree that chemical action must necessarily follow the action of light in a cell. For, take the case of the oldest photo-electric cell—the thermopile—what chemical action can we show here for all the energy of the solder heat. Chemical action due to light may, or may not, occur according to the nature of the cell. Mr. Appleyard asked whether the author had submitted these selenium resistances to the action of electric oscillations. Prof. Minchin's "impulsion" cells were greatly influenced by electric oscillations. The great variation in the resistance with time of the author's cells pointed rather to an effect of contact between the selenium and the electrodes, than to an elementary change in the structure or composition. He (Mr. Appleyard) had recently tried to crystallise a supersaturated solution of sodium sulphate by electric oscillations, as well as by direct sparks, and by currents of several amperes, but no crystals could be induced to form. Change of contact, rather than change of structure, appeared to him to be the most promising direction in which to look for an adequate theory of selenium resistances. Prof. Ramsay said the quantity of Se liberated in the electrolytic experiment was much too great to be accounted for by oxygen dissolved in the water. The study of Se was very interesting, for this substance was on the borderland between those bodies in which the electric conduction was metallic, and those in which it was known to be electrolytic. The author, in his reply, said he agreed that the name "selenium cell" was not an appropriate one. He had not tried the effect of electric oscillations. The Society then adjourned till the autumn.

PARIS.

Academy of Sciences, July 1.—M. Marey in the chair. The President announced the decease of Prof. Huxley, Correspondant of the Anatomy and Zoology Section.—On photographs of the moon and new objects discovered by means of them, by MM. Lœwy and Puiseux.—On an extensive class of linear partial differential equations, of which all the integrals are analytical, by M. Emile Picard.—Laws of extinction of a simple wave on the high seas, by M. J. Boussinesq. The coefficient of extinction (with the distance) of a simple wave is inversely proportional to the fifth power of its demiperiod T.—On the estimation of minute quantities of arsenic, by M. Ad. Carnot. The arsenic is separated in the usual manner as sulphide, this is dissolved in hot ammonia and treated with silver nitrate and hydrogen peroxide. The solution is then precipitated by bismuth nitrate, followed by ammonia, the accompanying bismuth hydrate is dissolved out by nitric acid (1 nitric acid of sp. gr. 1·33), and, finally, the bismuth arsenate is dried at 110° and weighed.—Truffes (Terfas) from Morocco and Sardinia, by M. Ad. Chatin.—Comparison of the heating of the muscles in the cases of positive and negative work, by M. A. Chauveau. During negative work, descent or lowering, the temperature of the muscles concerned was raised to a notably less degree than during corresponding positive work, ascent or raising.—Contribution to the study of arable soil. Quantities of air and water contained in soils of earth, by M. P. P. Dehérain.—On the products of sulphonation of benzylidenecamphor and benzylcamphor. Nitrate or nitronitrite of benzylidenecamphor, by M. A. Haller.—A new instrument (tacheograph) serving to survey and trace directly from the earth's surface, by M. Schrader.—On curves traced on a surface, of which the osculating sphere is tangential at each point to the surface, by M. E. Cosserat.—On linear equations to the derived partials, by M. Étienne Delassus.—On the integration of ordinary differential equations, by M. Alf. Guldberg.—On the propagation of sound in a cylindrical tube, by MM. J. Violle and Th. Vautier.—On the apparent attractions and repulsions of electrified conductors in a dielectric fluid, by M. Gouy. The apparent forces exercised between conductors with given charges in a liquid dielectric result: (1) from their mutual attractions and repulsions, the same as in a vacuum; (2) from the hydrostatic pressure produced by the force which attracts the dielectric in the sense where the intensity of the field increases most rapidly.—New method of measurement of electric capacities based on the sensitiveness of the skin, by M. H. Bordier.—On the solubility of superfused liquids, by M. Louis Bruner. The author finds that superfused sodium thiosulphate is much more soluble in alcohol than the corresponding solid compound.—On the specific heat of superfused salts, by M. Louis Bruner. The curve of specific heats at different temperatures for sodium thiosulphate shows a maximum near the point of fusion, 48° C.—On paratungstic acid, by M. L. A. Hallopeau.—On the estimation of alumina in phosphates, by M. Henri Lasne. A method of precipitation of pure aluminium phosphate is described, which avoids the complications introduced by the use of molybdate or citrate in estimating alumina. The precipitation is accomplished by the use of ammonium thiosulphate.—On sodammonium, by M. de Forcrand. A thermo-chemical study.—On the phosphoric esters of allyl alcohol, allylphosphoric acid, by M. J. Cavalier.—Preparation and conductibility of new methyl alkyleyanacetates, by M. J. Guinchant.—Verification of Tschermak's law relative to plagioclases, and a new process of orientation and of diagnosis of felspars in thin plates, by M. A. Michel-Lévy.

THURSDAY, JULY 18, 1895.

ANALYSIS OF OILS, FATS, AND WAXES.

Chemical Analysis of Oils, Fats, and Waxes, and of the Commercial Products derived therefrom. From the German of Prof. Dr. R. Benedikt. Revised and enlarged by Dr. J. Lewkowitsch, F.I.C., F.C.S. (London: Macmillan and Co., 1895.)

TEN or twelve years ago, the analysis of oils was one of the most neglected branches of analytical chemistry. How the study of it has been taken up and developed since, may be gathered by turning over the 670 pages of this excellent volume, the first English work devoted exclusively to this subject. The information existing in 1882 was comprised within 140 pages (much smaller than these) of Allen's "Commercial Organic Analysis." In the second edition of the same work, published in 1886, the subject-matter had grown to 318 pages. Benedikt's "Analyse der Fette und Wachsarten," second edition, published in 1892, upon which the present work is based, contained 460 pages, and as the literature of the subject has accumulated since then, at an increasingly rapid rate, it is evident that a new volume was demanded, the preparation of which could not have devolved upon any one more capable than Dr. Lewkowitsch, whose practical experience in, and valuable contributions to, our knowledge of this branch of chemistry are well known. To regard this work merely as a translation of the work of Dr. Benedikt would, obviously, be absurd. As the author points out in the preface, every page bears evidence of the alterations and numerous additions which have been made. Obsolete processes have been abridged or entirely omitted, and the new work of the last four years has been sifted, and all that is of value has been incorporated, including a large number of the author's own experiments and observations hitherto unpublished. Benedikt's arrangement of the subject-matter has been generally adhered to, but an improvement has been effected by transferring to the end of the book the chapter on the analysis of soap, candles, glycerine, and other products of the fat industry.

The first two chapters contain a description of the sources and chief properties of the various acids and alcohols obtained, or derived by oxidation, from the fats and waxes, followed by an account of the chemical constitution and the chief chemical and physical characters of the oils, fats, and waxes themselves. Commercial fats and oils are not pure neutral bodies, but always contain more or less free fatty acids which, for some purposes, depreciate their value. The percentage of free acid is liable to increase on keeping, and it was until recently believed that the development of rancidity was connected with this change. But Ballantyne has disproved this by showing that an oil may become rancid without becoming acid, and Heyerdahl has proved that the converse may also be true. The discovery, by Kirchner, of micro-organisms in poppy-seed oil, lent support to the view that rancidity might be the result of a fermentation process; but Ritsert showed that a fat which had been sterilised by heating to 140° C., might subsequently become rancid if exposed to light and air. The latter investigator has also shown that moisture is by no means essential, and he has finally concluded that rancidity must be due to the direct oxidation of the oil or fat by the oxygen of the air acting in presence of light.

Chapter iii. describes the determination of water and other non-fatty admixtures, and the preparation of the pure fat for analysis. Then follow a chapter on the physical properties and methods of examining fats, and four chapters on chemical methods. In the two next chapters the application of the foregoing, and some other methods, to the examination of fats is discussed, and data obtained by submitting the various oils, fats, &c., to examination by each method are collected and arranged in tables. This, however, is hardly shown by the headings of the chapters. Thus, chapter iv., which is headed "Physical Properties of Fats and Waxes," should rather be "Physical Properties and Methods of Examining Fats and Waxes"; and chapters ix. and x., headed "Systematic Examination of Liquid and Solid Fats and Waxes," with the sub-headings "Physical Methods" and "Chemical Methods," would be better entitled "Application of the foregoing Methods to the Systematic Examination," &c., with sub-headings "Application of Physical Methods" and "Application of Chemical Methods." These eight chapters are admirably written, and the value of the information given is greatly enhanced by the able manner in which each method is discussed and criticised. The completeness of the treatment shows how thoroughly the author has ransacked the literature of the subject. Unfortunately the task of reading and sifting papers is rendered heavier than need be by the growing tendency to rush into print with trivial and ill-considered observations. Thus, "the excellent *Reichert-Meissl* process has not escaped the fate of nearly all modern methods used in fat analysis" (there is no need to limit the statement to fat analysis, as the literature of steel analysis would show), "viz., to receive at the hands of numerous analysts a number of supposed improvements, most of which are altogether insignificant and hardly offer any advantage whatever." Again, referring to the Hübl process: "The chemical literature of the last few years contains numerous papers by various authors purporting to give improvements or modifications of the original method. Most of these refer to minor and unimportant points, and some of them even reproduce methods which Hübl in his classical paper has rejected."

For the determination of unsaponifiable matter, the author recommends petroleum spirit in preference to ether, but he very rightly insists upon the necessity of carefully purifying and rectifying the spirit used. If this is not done, some of the lighter mineral oils occasionally used to adulterate rape oil, for instance, may be lost, and for that reason I prefer to use ordinary ether, which can be completely expelled at a very moderate temperature.

For the determination of resin, Twitchell's process is recommended as yielding the best results, but no process yet exists by which resin can be determined with absolute accuracy.

"If a correct method of determining accurately the oxygen absorbed were known, it would be possible to class the determination of the drying power, or, as it might be called, the 'oxygen value' amongst the quantitative reactions." Such an addition to existing methods would be of the greatest value in the examination of the

N

various oils from cruciferous and other seeds which now pass under the name of "rape oil."

In the eleventh chapter, which extends over 273 pages, the natural oils, fats, and waxes are systematically arranged and separately described, a very excellent and most valuable feature being a series of tables appended to the description of each oil, fat, and wax, giving the physical and chemical constants (1) of the oil itself, (2) of the mixed fatty acids, and (3) of the wax alcohols. It is a pity these tables were not arranged so as to be readable without having to turn the book half round, which might have been done by cutting each table in half. No less than 106 oils, &c., are thus separately described, and their physical and chemical constants are collected and arranged in about 175 tables. The usefulness of these tables to the analyst cannot be over-rated, though it does not appear to be clear in all cases by what method the melting and solidifying points of the fatty acids were determined. The "saponification values" are expressed per mille, and the iodine and other values per cent., but there is no reason why the simpler plan of expressing all the quantitative values in percentages should not be adopted. The section on butter fat, the analysis of which was the first to be placed upon a scientific basis, occupies twenty-three pages.

In chapter xii. the analysis of the raw materials and products of the fat and oil industries is treated, and in the concluding chapter some examples of the interpretation of results are given; but space does not admit of further reference.

This book is unique: the analyst will find in it practically all the available information upon the subject up to date, with full references to the original papers; and it will increase the author's already high reputation.

L. ARCHBUTT.

TRACES OF A DELUGE.

On Certain Phenomena belonging to the Close of the last Geological Period, and on their bearing upon the Tradition of the Flood. By Joseph Prestwich, D.C.L., F.R.S., &c. (London: Macmillan and Co., 1895.)

HAD the story of the Deluge a foundation in fact; in other words, is it a record of some inundation which affected a considerable area of the earth's surface? This is the question which Prof. Prestwich sets himself to answer in the small volume before us—a volume which combines a paper read to the Victoria Institute with some of the material communicated to the Royal and the Geological Societies.

In the south of England, especially in the neighbourhood of the coast, a drift is often found, varying in thickness from a few inches to a few feet, which consists of angular fragments of rock with loam derived from adjacent higher ground, and lies on the slopes of the hills and at the bottom of the valleys. Frequently it is absent, but where hollows occur in the surface of the underlying rocks, it has accumulated in greater quantities, and occasionally even exceeds eighty feet in thickness. In some localities it rests on an old raised beach, and is banked up against a buried sea cliff; in others it fills up fissures in the rocks. In the last case it frequently contains the bones of mammals, many of them now extinct—at any rate in Britain. These are neither worn nor gnawed, but are commonly broken and split. Its fossils, almost without exception, are of terrestrial origin. Similar deposits occur in the Channel Isles and on the French coast, and in many places around the Mediterranean, not to mention others. What is the origin of this "rubble drift," "head," osseous or fissure breccia?

Prof. Prestwich refers all these deposits to one epoch of very limited duration. He supposes that there was a rather widespread subsidence, amounting, in some places, to a few hundred feet, during which the sea overflowed the lower land. This was sufficiently rapid to make the invading water muddy; then, before the marine molluscs had time to establish themselves in the new territory, the land was upheaved by jerks (with intervening pauses). These sudden disturbances of its bed set up currents in the sea, strong enough to sweep heavy débris, and even largish blocks of rock, from the higher to the lower ground, and to precipitate the material into any open fissures. By this tumultuous action the bones of the terrestrial mammals which had been drowned by the submergence would be dispersed and shattered, and it explains, in his opinion, all the phenomena better than any other hypothesis. As man was living at the time, it gave rise to the tradition of the Flood.

An adequate discussion of Prof. Prestwich's hypothesis is impossible in our limited space; but we may be permitted to remark that it is not free from serious difficulties. Many geologists would dispute the assumption that these deposits all belong to one and the same epoch. Others will doubt whether the sudden upheavals, which he postulates, would be adequate to produce currents, capable of moving the larger débris, or whether the earth movements would suffice, as he supposes, to make gaping fissures. Some will think that he hardly appreciates the effect of "cloud bursts," such as may be seen in many mountain and even lowland districts of Europe, in transporting débris very similar in character to the "head." It is admitted that since this was deposited denudation has wrought some changes in the contours of the country, and this may explain the apparent isolation of some patches of the "head," whether it fill fissures or cap tabular hills. In several cases the ordinary explanation of breccias (admitting as an adjunct the action of snow) seem to us more simple than that proposed by Prof. Prestwich, and his mode of accounting for the abundance of hippopotamus bones at San Ciro, near Palmero (that as the land sank they were embayed between its precipitous face and the advancing sea, and at last were drowned) can hardly be called probable. Lions and hyænas might have perished in that way, but the hippopotamus seems far from helpless in the water, and is likely to have saved itself.

We think, then, that Prof. Prestwich's hypothesis will be received with some scepticism; nevertheless, it demands careful consideration as an attempt to solve a very difficult problem, which is put forward by one who may now be termed the Nestor of British geologists, and who has paid especial attention to questions of this nature.

AN ECLECTIC HISTORY OF SCIENCE.

Progress of Science. By J. Villin Marmery. Pp. 357. (London: Chapman and Hall, Limited, 1895.)

THE custom of inserting laudatory prefaces or introductions, written by well-known men, in works of science by lesser lights, which was commented upon in these columns a few weeks ago, reaches the ridiculous in the case of this book. A letter from Mr. Samuel Laing to the publishers is printed, in the course of which he says: "I have now had time to read Mr. Marmery's book, and find it a work of great learning and research . . . and I can confidently recommend it as alike interesting and instructive." What induced the publishers to print this purely business letter as a testimonial to the book's good qualities, passes our comprehension. A book usually finds its proper level, and the effort to force it into a higher position by means of a letter of introduction from a more or less distinguished individual, must prove futile: for in literature, scientific or otherwise, authors are judged entirely by their own works.

Every one will recognise that to attempt to condense the history of science into a volume of about three hundred and fifty pages, is to court failure. All that can be accomplished in so small a space is to describe the well-defined steps of advancement along the road of natural knowledge, and to exhibit the continuity of scientific developments. Mr. Marmery has done this with a fair amount of success. After briefly noting the knowledge of the Egyptians and Chaldeans so far back as 3000 B.C., he surveys the successive stages in the history of science, and devotes a few lines to men and matters of first-rate importance in each. His statement of the progress made by the Arabians from the ninth to the fifteenth centuries, brings into view the substantial achievements of a people which then stood in advance of the whole world. Our obligations to the Arabs are indubitable; nevertheless, few European historians have expressed them. "Eminence in science is the highest of honours" was a maxim which represented the bearing of Islam towards scientific knowledge at a period when Europe was ruled by monkish philosophy, and when investigators were stamped as heretics.

The review of the science of the Greek, the Arabian, the Mediaeval, and the Revival periods, leads to the science of the Modern period, from the end of the sixteenth century to the present time. And here the author treads upon dangerous ground. He has had, perforce, to create invidious distinctions by selecting from the host of scientific workers those that appear to him to have added most to the store of knowledge. Huxley got over the difficulty in his address on "The Progress of Science," published among his collected essays (vol. i.), by omitting references to all living men, and by dealing only with results. Mr. Marmery might have saved himself from hostile criticism by following the same method; but, in that case, his volume would have wanted the very information which is the chief justification for its existence. His selection of names has, he says, been determined "by what appears *typical originality* in the work, rather than by what is imposing in extent and weight." Here and there we fancy this criterion has not been applied; but in a book covering so wide a scope, such deficiencies may well be excused. Modern investigators are divided into seven groups, viz. (1) biologists, (2) geologists, (3) chemists, (4) mathematicians, (5) astronomers, (6) physicists, (7) eminent practical men. Short accounts of the main achievements of the individual workers in each group are given, and are fairly trustworthy. In an appendix, the names of foremost men of science in all the periods are tabulated, and a copious index makes it easy to find the sketch of the works of any one of them.

Many imperfections the book certainly has, but in spite of them we think it deserves some words of commendation. Those who wish to know something about the evolution of scientific knowledge, and the multitude of readers who like to dip into a book to find what this or that man of science has done, may obtain from this handy volume the information they seek. We could easily enumerate a score of names which ought to find a place in the book, but are wanting. Probably it was because the author was aware of the incompleteness of his record, that he omitted the definite article from the title of his book.

MICROSCOPIC STUDY OF ROCKS.

Petrology for Students: an Introduction to the Study of Rocks under the Microscope. By A. Harker. (Cambridge University Press, 1895.)

THIS latest addition to the Cambridge Science Manuals is intended by the author as a guide to the study of rocks in thin slices under the microscope In scarcely another English text-book on the subject has the treatment of rocks from the purely petrographical point of view of microscopic examination been so strictly adhered to throughout as in the book before us. "Microscope" is almost the first word in the book, and sounds the key-note of the whole.

After a short introduction, containing a few notes on the optical properties of minerals, the author plunges at once into the systematic description of the different rock species. The usual chapters on the characters and methods of separation and determination of the rock-forming minerals are omitted altogether; for all such mineralogical points, the reader is referred to standard works on the subject. The book, therefore, corresponds, though on a much smaller scale, to the second volume of such text-books as those of Rosenbusch and Zirkel.

In the classification of the massive igneous rocks the author divides them into *plutonic*, *intrusive* and *volcanic*, but is careful to point out that the divisions themselves are based upon the *structural* characters resulting from the different conditions of consolidation. This classification resembles that of Rosenbusch, but the author's intrusive groups do not correspond exactly with the Ganggesteine of Rosenbusch, for he extends them to the basic family, whereas even Rosenbusch considered this to be impracticable. In this connection we notice that those much abused terms "diabase" and "porphyrite" receive new definitions. Diabase is in this book used to designate, not pre-Tertiary or altered dolerites, but the group of intrusive basic rocks corresponding to the volcanic basalts, while porphyrite is applied to the intrusive rocks corresponding to the volcanic andesites. The author, of course, follows the British school in admit-

ting no criterion of geological age in the nomenclature of the rocks.

Throughout the book, each rock group is treated for the most part under the three headings: constituent minerals, structure, illustrative examples. Under the last heading, purely petrographical descriptions are given of typical examples, chosen generally from British rocks.

The sedimentary rocks are treated under the divisions, arenaceous, argillaceous, calcareous, and pyroclastic. In perhaps no other English text-book have the microscopic characters of the sedimentary rocks been so minutely described. The subject of metamorphism is treated under the two heads of thermal metamorphism and dynamic metamorphism, and the effects produced on arenaceous, calcareous, argillaceous and igneous rocks are separately described. The book concludes with a short chapter on various crystalline rocks, including gneisses, granulites, &c. It is, perhaps, almost inevitable, owing to the nature of the subject, that the book should give the general impression of consisting of a series of descriptions of rock-sections; but, be this as it may, there can be nothing but praise for the clear and straightforward way in which the author has presented his facts, and for the wealth of new matter which the book contains. The book shows evidence of most careful research into the literature of the subject, and is in fact thoroughly up to date, containing many extracts from papers which have appeared within the present year.

G. T. P.

OUR BOOK SHELF.

Garden Flowers and Plants: a Primer for Amateurs. By J. Wright. With fifty Illustrations. (London: Macmillan and Co., 1895.)

ONE of the great advantages of gardening and of a love of flowers consists in the fact that they may be indulged in by rich and poor alike.

The rich have no monopoly in the beauty of flowers, the poor are not debarred from their enjoyment. The costliest orchid in a ducal garden is not one whit more beautiful than an Iris which may be bought for a few pence. If a slug devour the one it is easily replaced, if such an accident befall the other the loss may be beyond repair. Nor by those who look beneath the surface and seek to penetrate the significance of the diversity of form, and the meaning of the beauty they witness, is costly expenditure needed. The cheapest and commonest afford as copious materials for research and investigation as the dearest plant in the nurseryman's price list. Anything that will lighten the sordid conditions under which so many of the poorer classes live, anything that will brighten their homes and give them an interest in something beyond their daily toil, must be considered as a boon of incalculable value. Such a boon is offered by the pursuit of gardening. In country districts, moreover, where small gardens and allotments can be had, gardening may be made to add considerably to the resources of the family. It may be doubtful whether market gardening on a large scale will always be profitable, but there can be no doubt that the small plot of the labourer may be turned to good account, provided circumstances are even only moderately favourable. To provide for the needs of small gardeners and amateurs, Mr. Wright has published the little manual before us. The author is an accomplished practitioner, and his experience as a County Council lecturer has enabled him to ascertain precisely what is wanted by his auditory. Mr. Wright begins at the beginning by telling his readers how to make a garden, how to lay down gravel walks, what to grow on walls, what on beds, even what may be cultivated in areas. The principal categories of hardy plants are passed in review, such as annuals, perennials, bulbous plants, bedding plants, and so on, and clear directions are given as to their management from beginning to end. In all this there is not much that needs comment from a reviewer, who can only say that the little primer is well done, and excellently suited for its purpose.

An explanation of the real cause of "damping" off would have been of value, as the most "practical" of gardeners is not desirous of cultivating fungus at the expense of cherished seedlings.

The small illustrations are helpful, and a full index adds materially to the value of the book.

The Time Machine. By H. G. Wells. (London: Wm Heinemann, 1895.)

INGENIOUSLY arguing that time may be regarded as the fourth dimension of which our faculties fail to give us any distinct impression, the author of this admirably-told story has conceived the idea of a machine which shall convey the traveller either backwards or forwards in time. Apart from its merits as a clever piece of imagination, the story is well worth the attention of the scientific reader, for the reason that it is based so far as possible on scientific data, and while not taking it too seriously, it helps one to get a connected idea of the possible results of the ever-continuing processes of evolution. Cosmical evolution, it may be remarked, is in some degree subject to mathematical investigations, and the author appears to be well acquainted with the results which have been obtained in this direction. It is naturally in the domain of social and organic evolution that the imagination finds its greatest scope.

Mounted on a "time-machine" the "time-traveller" does not come to a halt until the year eight hundred and two thousand, and we are then favoured with his personal observations in that distant period. In that "golden age," the constellations had put on new forms, and the sun's heat was greater, perhaps in consequence of the fall of a planet into the sun, in accordance with the theory of tidal evolution. "Horses, cattle, sheep, and dogs had followed the ichthyosaurus into extinction"; but, most remarkable of all, "man had not remained one species, but had differentiated into two distinct animals," an upper-world people of "feeble prettiness," and a most repulsive subterranean race reduced to mere mechanical industry. It is with the time-traveller's adventures among these people, and their relations to each other, that the chief interest of the story, as such, belongs.

Continuing his journey to an age millions of years hence, nearly all traces of life had vanished, the sun glowed only with a dull red heat, tidal evolution had brought the earth to present a constant face to the sun, and the sun itself covered a tenth part of the heavens. These and other phenomena are very graphically described, and from first to last the narrative never lapses into dulness.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Teaching University for London.

I HAVE read with surprise your article on the University of London.

Probably by some accident you had not seen my reply to Lord Kelvin's letter when you went to press. I now enclose a copy, and trust to your fairness to insert it:

"*2 St. James's Square, S.W., July 9.*

"MY DEAR RÜCKER,—I am sorry I could not immediately answer the letter which you have forwarded to me on behalf of

Lord Kelvin and other members of the Royal Society, but I only received it this morning, as I was away from home. I observe that most of those who have signed it are (as they themselves say) not members of Convocation, and consequently not constituents of mine. Still, I should welcome any opportunity of co-operation with such high authorities in the promotion of those interests which we all have at heart. I regret, however, that before publishing the letter they did not give me an opportunity of conferring with them, in which case, I think, I could have given good reasons for what I have said in my letter to Prof. Foster. I am glad to observe that the only point objected to is the reference of any new charter to Convocation. In this, however, I am not asking that any privilege which they do not at present possess should be conferred on my constituents, but only supporting what is now their legal right. As the law now stands no change can be made in the charter without the consent of the graduates. This right I know they highly value, and it is surely natural that, as their representative, I should do my best to preserve it. Moreover, in view of the difficulty of passing a Bill strongly opposed, as any Bill would be, which seeks to abrogate the present right of veto possessed by Convocation, I can imagine nothing more likely to wreck any scheme such as you desire than to link it, quite unnecessarily, with an attack on that right. Your objection to the reference to Convocation implies the belief that a Statutory Commission would arrange a wise charter for the University, and that the graduates would reject it. But why should it be assumed that they would do so? It has been my proud boast that I represent a constituency second to none in education and ability, and I am sure you will not, on reflection, be surprised if I have every confidence that when any new charter is submitted to my constituents, they will exercise the rights well and wisely, and with an earnest wish to further the interests of Learning and Education.

"I am, yours very sincerely,
"JOHN LUBBOCK."

I must also ask you to let me say a few words on your own article.

In the first place, I have not "accepted the views" of those who altogether oppose the Reorganisation Scheme. Some, indeed, of the modifications suggested seem to me important improvements, but that is a very different thing.

You say that Convocation is only one of the bodies affected. In the case of the Colleges and Medical Institutions certain privileges are granted, but the University is the only body whose constitution it is proposed to change.

At present, this cannot be done without the consent of Convocation, and you blame me for endeavouring to maintain that right. Your whole article assumes that the Commissioners will make a wise scheme, and then you allege that a reference to Convocation would wreck it. This, however, is an attack on my constituents and not on me. JOHN LUBBOCK.

High Elms, July 15.

The Density of Molten Rock.

IN a review of Lord Kelvin's "Geology," in NATURE, July 26, 1894, vol. l. p. 292, the question of whether solid rock sinks or swims in molten rock was left open for further experimental evidence.

My impression is that this was in accordance with the views of the writer of the book; but if I had had proper acquaintance with the work of Mr. Carl Barus, of the Smithsonian Institution, Washington, I should at least have referred to it. Permit me to do so now, and to give the references:—*Am. Journ. of Science*, 1893, vol. xlv. p. 1; *Phil. Mag.*, 1893, vol. xxxiv. p. 1; vol. xxxv. pp. 173 and 296; also certain *Bulletins* of the U.S. Geological Survey, particularly No. 103, which contain the most complete account. OLIVER J. LODGE.

The Earliest Magnetic Meridians.

IN NATURE of June 6, p. 129, Captain E. W. Creak, F.R.S., questions a statement of mine with regard to this subject, as published in NATURE of May 23, p. 80. I there credited Yeates instead of Duperrey with the first construction of the magnetic meridians for the whole earth. I was careful not to say that Yeates *originated* the idea of magnetic meridians.

Euler, to my knowledge, about the middle of last century, appears to have first appreciated the importance of those lines from a theoretical standpoint. He defines them as those curves on the earth's surface, the tangents to which mark out the actual direction of a compass needle. He did not actually construct them, however, if I remember correctly.[1]

It was my belief then that Yeates first drew these curves, as based upon observations. Captain Creak, however, thinks that John Churchman deserves this honour.

So far as I know, Churchman published but two magnetic charts or atlases, one in 1790, the other in 1794. The chart referred to by Captain Creak is the earlier one, if I mistake not. A text to this chart was also published, called "An Explanation of the Magnetic Atlas," Philadelphia, 1790. It was my belief that this was an isogonic chart a chart giving the lines of equal variation—not a chart of the magnetic meridians. Churchman's later work, "The Magnetic Atlas or Variations Charts," London, 1794, contains charts which, according to Prof. Hellmann, are more theoretical. Prof. Hellmann mentions and briefly describes both of Churchman's charts, and gives the impression that they are isogonic charts.[2]

As I have no means at present of verifying this matter, may I ask Captain Creak to make further examination, and state if Churchman's magnetic meridians are based upon observation? L. A. BAUER.

The University of Chicago, June 29.

Curious Habit of the Spotted Flycatcher.

I HAVE been watching, at intervals during the last week, a pair of Spotted Flycatchers feeding their young in a nest on a ledge of the wall of this house. The nest is embowered by a very free blossoming white rose. I noticed to my surprise the parent birds again and again, after taking food to their offspring, plucking off the petals of the rose near the nest, and transporting them to an acacia tree about ten yards distant, where they let the petals drop upon the ground. The rose blossoms are now quite cleared away from the neighbourhood of the nest, and the lawn beneath the acacia thickly strewn with them.

The rose flowers do not obstruct the approach to the nest, to which the birds have access by running a short distance along the ledge. It is also difficult to suppose that the object of the birds is to admit more air and light to the nest, which is more open to the sunlight than very many nests of this species which I have found. Moreover, the birds take no trouble to remove any of the dead leaves which are near the nest, having an objection, as it appears, only to the blossoms of the rose. I can offer no explanation of this curious conduct of the flycatchers. W. CLEMENT LEY.

Tellack Vicarage, Ross, Herefordshire, July 11.

A Brilliant Meteor.

ON Sunday, July 7, about 10.45 p.m., I observed a meteor of rather peculiar character. Contrary to the general method of appearance of these objects, it came into view very gradually, and its motion was so uniform and slow that its form could be clearly discerned.

The meteor was double, the two components being about $\frac{1}{4}°$ apart, but travelling together, the smaller one being ahead of the larger. The combined magnitude was probably equal to that of Venus as seen earlier on the same evening.

Some trace of trail could faintly be made out, but this was rendered uncertain by the sky being very luminous in consequence of the moon's position near the meridian at the time.

While visible the meteor travelled about 20° in a path approximately parallel to the horizon, and a rough estimate of its position would be:

	R.A.	Decl.
Appearance ...	... 13h. ...	+ 20
Disappearance	... 11h. 30m. ...	+ 35

No explosion of any kind was noticed, nor any accompanying sound. CHARLES P. BUTLER.

Royal College of Science, July 9.

Newton and Huygens.

UPON Newton's conception of the universe, space is considered to be void. A fluid or gas would oppose resistance to the motion of the planets, and however small this resistance might be, it would cause a diminution of the linear velocity of the planets. The central attraction being unchanged, a diminution of the linear velocity of the earth

[1] See Gehler's "Physikalisches Woerterbuch," article "Magnetismus."

[2] "Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus," No. 4, p. 22.

would cause an augmentation of its angular velocity around the sun. The period of revolution would take less time, and the length of the year would gradually decrease. Observation proves that this is not the case, and the necessary conclusion is, that there is no resisting medium in space, which must be, therefore, considered as perfectly void.

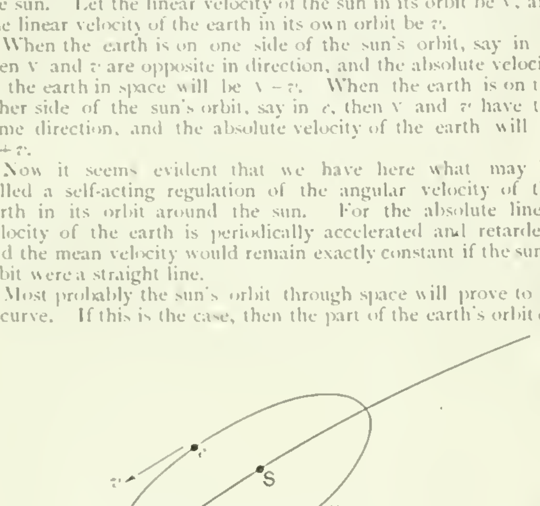
There is no objection to be made to this reasoning so long as we suppose the sun immovable in space, which was the generally accepted belief in Newton's time. But we know at present that the sun, with all the planets, has a motion through space: and this knowledge changes the conditions of the problem, as may be demonstrated by what follows.

In the accompanying figure, S is the sun in a certain point of its orbit in space. E is the earth in a certain point of its orbit around the sun. Let the linear velocity of the sun in its orbit be V, and the linear velocity of the earth in its own orbit be v.

When the earth is on one side of the sun's orbit, say in E, then V and v are opposite in direction, and the absolute velocity of the earth in space will be $V - v$. When the earth is on the other side of the sun's orbit, say in e, then V and v have the same direction, and the absolute velocity of the earth will be $V + v$.

Now it seems evident that we have here what may be called a self-acting regulation of the angular velocity of the earth in its orbit around the sun. For the absolute linear velocity of the earth is periodically accelerated and retarded, and the mean velocity would remain exactly constant if the sun's orbit were a straight line.

Most probably the sun's orbit through space will prove to be a curve. If this is the case, then the part of the earth's orbit on



the concave or outer side of the sun's orbit will be somewhat longer than the part on the convex or inner side.

If this be so, then the acceleration on the outside part will be somewhat greater than the retardation on the inner side of the earth's orbit. Thus the surplus velocity, gained in each revolution around the sun, will compensate the loss of linear velocity which the earth might suffer in its yearly orbit around the sun by the resistance of a supposed medium in space.

It might, however, be asked, Why it is that this compensation is so exact as we find it to be? For Laplace, in his well-known work on the "Système du monde," explains clearly that no change in the period of revolution of the earth around the sun has been observed.

But we may quite as well wonder why the temperature of our blood is nearly constant; and the best answer to such questions is in the well-known words: "Philosophy does not ask what agrees, but what is."

The sun's motion in space is a discovery with far-reaching consequences for science in general; and if space be allowed, a few other corollaries must follow upon it. For the present, it is better to limit research to the single question as to whether we may admit the existence of a resisting medium in space. The answer is that the discovery of the sun's motion in space allows us to settle this much disturbed question in a positive sense.

This result has a particular value, because it takes away the contradiction between two theories which are both generally admitted. The undulatory theory of light, which was first enunciated by Huygens, supposes the existence of an elastic medium in space. When it is demonstrated that the supposition of this medium is not incompatible with Newton's theory of central forces as applied to our planetary system, this must certainly be considered as a step in advance.

A. HUET.

Delft, Holland, July 5

THE INTERNATIONAL CATALOGUE OF SCIENTIFIC PAPERS.

THE following report of the International Catalogue Committee was presented to the President and Council of the Royal Society on July 5, and the recommendations contained in it were approved.

At the first meeting of this Committee (February 8, 1894), the Memorial to the President and Council (July 1893) which led to the appointment of the Committee, and the Minute of Council of December 7, 1893, appointing the Committee, having been read, it was resolved to request the President and Council to authorise the Committee to enter directly into communication with societies, institutions, &c., in this country and abroad, with reference to the preparation, by international co-operation, of complete subject and authors' catalogues of scientific literature.

Subsequently, a draft circular letter was prepared, which, on February 22, 1894, received the approval of the President and Council, who also authorised its issue.

This letter was sent to 207 societies and institutions selected from the exchange list of the Royal Society, and to a few others. It was also sent to the Directors of a number of Observatories and of Government geological surveys, to the Foreign Members of the Royal Society, as well as to those of the following Societies: Chemical, Geological, Physical, Royal Astronomical, Linnean, Royal Microscopical, Entomological, Zoological, Physiological, and Mineralogical, and of the Anthropological Institute. A special letter was addressed to the Smithsonian Institution.

More than a hundred replies to the letter have been received; several of these are reports of Committees specially appointed to consider the suggestions put forward by the Royal Society. A list of answers received up to December 1894, with brief excerpts from the more suggestive, was issued to members of the Committee early in this year. It should, however, be added that from some important institutions no answer has as yet been received.

It may be said at the outset that in no single case is any doubt expressed as to the extreme value of the work contemplated, and that only two or three correspondents question whether it be possible to carry out such a work. It is a great gratification to the Committee that the matter has been taken up in a most cordial manner by the Smithsonian Institution, the Secretary of which, in his reply, refers to the desirability of a catalogue of the kind suggested as being so obvious that the work commends itself at once. The importance of having complete subject catalogues, and not mere transcripts of titles, is also generally recognised.

Some bodies and individuals take the matter up very warmly and urge that steps be taken forthwith to put the scheme into action, this being especially true of the replies received from the United States; others, while giving a general approval, dwell upon the difficulties of carrying out the suggestions put forward; and others, again, ask for more details before committing themselves to any answer which may seem to entail future responsibility, especially of a financial character.

Incidentally it may be pointed out as very noteworthy that over and over again reference is made to the great value of the Royal Society's "Catalogue of Scientific Papers." There is abundant evidence that considerable use is made of this on the continent of Europe. And it is clear that a proposal to carry out a more comprehensive scheme initially under the direction of the Royal Society of London is likely to meet with general approval owing to the fact that the Society is credited with having already carried out the most comprehensive work of the kind yet attempted. Indeed, the Academy of Natural Sciences of Philadelphia, U.S.A., directly advocates the

establishment of a central bureau under the Royal Society; and several others more or less clearly imply that they would favour such a course.

Over and over again, it is stated that the production by international co-operation of a catalogue such as is contemplated is not only desirable, but practicable. The Americans who, as already stated, are the most enthusiastic supporters of the scheme, especially dwell on the importance of early action being taken. Prof. Bowditch, of Harvard University, in particular, points out that if the Royal Society of London wish to guide the enterprise, it ought to announce its views and put forward a comprehensive scheme with the least possible delay. It may be added here that he also urges that in determining the scope of the catalogue a very wide interpretation should be given to the word "Science."

No very precise information as to the best mode of putting the scheme into operation is to be gathered from the replies as a whole.

It is generally agreed that the enterprise should be an international one. Many think that international financial support should and would be accorded to it, but no method of securing this is indicated; others express the view that the cost may be met by subscriptions from societies, libraries, booksellers and individuals without Government aid, and this is, perhaps, on the whole, the prevailing feeling among those who have discussed the matter from a financial point of view. But in no case is any attempt made to form any exact estimate of the cost.

A number of scientific bodies and institutions express themselves prepared to work in such a cause. The Secretary of the Smithsonian Institution suggests that as the Institution receives all the serials and independent works published in America, a branch office might be established there, and that it is not impossible that a sum of money might be given yearly in aid. The Royal Danish Academy is willing to render as much assistance as possible. It would charge an official of one of the Danish chief libraries in receipt of all Danish publications with the task of editing slips, and would defray the cost of this work. The Société des Sciences of Helsingfors would furnish the central office with information as to the scientific work done in Finland. The Kongl. Vetenskaps Akademie of Stockholm would organise a Committee for Sweden.

As regards language, there appears to be more unanimity than could have been expected. Over and over again the opinion is expressed that English should be the language of the subject catalogue. Frequent reference is made to the importance of quoting titles in the original language, although some suggest that this should be done only in the case of those published in English, French, or German, and perhaps Italian.

Some form of card catalogue appears to be generally favoured, especially in America, as the basis of the scheme; the Committee of Harvard University, whose reply is very full, in particular discuss this point in detail.

In an interview with the Committee in March last, Prof. Agassiz spoke very warmly in favour of the scheme, and of the support which it would meet with in the United States, especially from libraries. As others have done, he strongly urged that the co-operation of booksellers and authors should be secured. Prof. Agassiz also expressed the view that the regular issue to libraries and scientific workers from the central office of cards or slips which would afford the material for the construction of card catalogues would form an important source of income, at all events in his country.

From various sides it is urged that an International Congress should be held to discuss plans. This is advocated as a first step in a reply received from the Königl. Gesellschaft der Wissenschaften in Göttingen, a reply to which, not only as regards this point, but also in respect to the whole matter, the Committee attach very great weight, since it embodies in an official form views arrived at by the academies of Vienna and Munich, and by the scientific societies of Leipsic and Göttingen, who have considered the matter in common. Prof. Agassiz strongly urged the calling of a conference, and among others who share this view, Dr. Gill, of the Cape Observatory, in his letter particularly dwells on the great value of such meetings as the means of securing unanimity of action.

Such being the tenour of the correspondence, your Committee are convinced that initial steps of a definite nature in furtherance of the scheme ought now to be taken.

They accordingly request the President and Council to take measures with the view of calling together, in July of next year (1896), an International Conference, at which representatives of the several nations engaged in scientific work should be invited to attend, with the view of discussing and settling a detailed scheme for the production by international co-operation of complete authors' and subject catalogues of scientific literature.

London will probably be found the best place in which to hold such a conference. It may be desirable to summon the representatives of the different countries through their respective Governments, and it will obviously be necessary that a detailed scheme be prepared, to serve as a basis for discussion at the conference. These and other points will require much consideration before any action at all can be taken; meanwhile, it is desirable that a beginning should be made during the autumn, before the winter session of the Society. The Committee therefore recommend that the President and Council should give the Committee (which includes the President and officers) executive powers in order that they may take, in the name of the Society, such steps as they may think desirable with the view of calling together the above-mentioned conference.

SCIENCE SCHOLARSHIPS AT CAMBRIDGE.

WITHIN the past academical year an attempt has been made by the college tutors at Cambridge, in consultation with representatives from Oxford, to come to an understanding as to the times at which examinations for entrance scholarships shall be held. Headmasters have frequently complained of the interruption to school work caused by the present somewhat haphazard arrangements, and have suggested the grouping of colleges and other expedients in mitigation of the difficulty. Some of the colleges, notably Caius, Jesus, Christ's, and Emmanuel, Pembroke with King's, and Clare with Trinity Hall, have agreed to group their examinations, candidates entering for the combined examination being required to indicate the colleges, in the order of their preference, which they desire to join if successful. The larger colleges, Trinity and St. John's, have for various reasons found it impracticable to form such combinations; but they have agreed at least to avoid clashing by fixing their examinations about a month apart. Nine of the colleges offer scholarships and exhibitions for natural science, the rest confining the competition to the old-established subjects of classics and mathematics. In the ensuing academical year, examinations in natural science for these awards will be held as follows: at Trinity, November 5; at Peterhouse (physical sciences only), November 19; at the group Caius, Jesus, Christ's, Emmanuel—November 26; at the group Pembroke, King's—and also at St. John's College, December 3; at Sidney, Sussex, December 12; at the group—Clare, Trinity Hall—January 1; and at Downing, about March 17. The value of the scholarships varies from £80 to £40 a year, of the exhibitions from £50 to £20. They are usually tenable for three or four years, with a condition that by the end of the second year the scholar shall have

approved himself sufficiently in the college examinations. Scholars are practically required to become candidates for honours in the natural sciences tripos, though the new mechanical sciences tripos will no doubt attract some. The new Salamon scholarships at Caius are, indeed, specially intended for students of engineering. It should be added that candidates for scholarships, who are not yet members of the university, must be under nineteen years of age; there is no restriction of age in respect of the science exhibitions. Though only nine colleges specifically offer entrance scholarships in science, an examination of the awards to the first, second, and third year students shows that in many more good work in science, as tested by university or inter-collegiate examinations, does not go unrecognised. The large body of medical students, now approaching five hundred in number, is distributed over all the colleges, and their presence has apparently brought home, even to the most conservative, the fact that intellectual ability, high-minded devotion to study, and social energy are not confined to students of classics and mathematics alone. Thus, though something remains to be done in certain quarters in the direction of placing science on an equal footing with the older subjects as a fit object of college recognition and reward, it must be owned that a great advance has been made within the last ten years. The natural sciences tripos now attracts a larger number of candidates than any other, and this notwithstanding that its standard has steadily been raised. In the majority of the colleges, distinguished eminence in this tripos has been admitted as a qualification for a fellowship, and in not a few instances governing bodies have felt the need of strengthening themselves on the side of science, and have departed from Cambridge custom by selecting scientific members of other colleges for this honour.

The endowments for research, other than scholarships and fellowships, have in late years been substantially increased. In addition to post-graduate studentships at the larger colleges, such as the Hutchinson at St. John's (physical and natural science), the Coutts-Trotter at Trinity (physics and physiology), the Frank Smart at Caius (botany), the university has of late received a number of benefactions for the same purpose. The Balfour studentship in animal morphology, worth £200 a year, the Harkness scholarship in geology about £100, the Clerk Maxwell scholarship in physics about £185, the John Lucas Walker studentship in pathology £200 to £300, the Isaac Newton studentships (three) in astronomy £200, and the Arnold Gerstenberg studentship, for natural science students pursuing philosophical study, about £55, are among these recent foundations. They are expressly intended to foster advanced study and research, and they have already produced excellent results. The university still lacks the means of providing similar encouragements for higher work in chemistry, in anatomy and anthropology, in botany, in mineralogy, in physiology, in pharmacology, and in scientific engineering. It is to be hoped that the line of generous benefactors is not yet extinct, and that some of these important subjects may ere long receive the benefit of their munificence. The new scheme for the promotion of post-graduate study and research, which has received the approval of the senate, and now only awaits the assembling of Parliament for the sanction of the necessary statutes, will render such endowments opportune and fruitful.

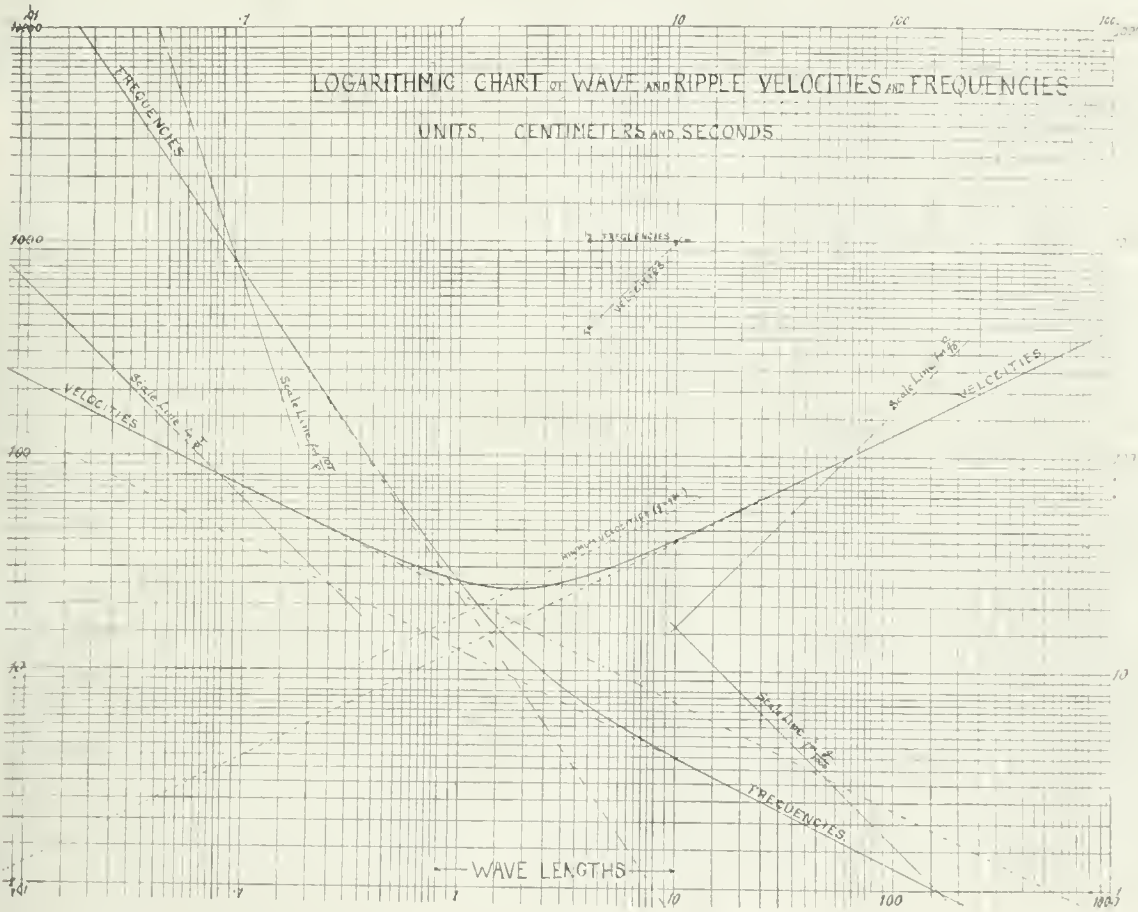
SCALE LINES ON THE LOGARITHMIC CHART.

THE advantages of logarithmic plotting for certain classes of work have for some time been recognised, and now that, thanks to Mr. Human, logarithmically ruled paper can be obtained ready made, the facility of such plotting is greatly increased, so that there is all the more reason on this account why it should become more common than it seems to be at present. It may perhaps be well to point out shortly what the nature and effect of logarithmic plotting is, and to contrast it with the more common method on square-ruled paper. Instead of paper ruled in equal squares, logarithmic paper is ruled first in a series of large equal unit squares representing tenfold changes in the coordinates. Thus two units represent 100, three units 1000, and so on. Similarly the squares are broken up fractionally and unequally into a series of vertical and horizontal lines, whose distance from the left or lower side of the square is equal to the logarithms of the numbers 2, 3, 4, &c., and these are subdivided again logarithmically just in the same way that a slide rule is subdivided. In fact, if logarithmic paper is not available, logarithmic plotting can still be carried out fairly expeditiously by pricking off distances direct from a good slide-rule. The meaning of lines drawn upon logarithmic paper is very different from that upon ordinary square ruled paper. For instance, an inclined straight line ruled in the ordinary way represents the equation $y = a + bx$, whereas when logarithmic paper is employed the corresponding line gives $y = ax^b$. The consequence is that whenever two quantities are related so that one varies as any power, positive, negative, integral, or fractional of another, a straight line drawn in the proper position and inclination represents that relation, the power being equal to the trigonometrical tangent of the angle of slope of the straight line. If the relation that is to be represented is less simple, if the index changes gradually as either of the coordinates changes, so that a curve has to be employed, then the size and shape of the curve represents the law in the abstract, and the position of the curve on the sheet the actual numbers for the particular case and with the particular units; a mere shift of the curve bodily upon the chart, as pointed out by Prof. Osborne Reynolds long ago, being all that is necessary to adopt the same law to new circumstances or new units.

One very important feature of logarithmic plotting is the fact that, not only is it practicable to include an enormous range (in Mr. Human's sheets of four by five squares of 10,000 and 100,000 in the two directions), but the proportionate accuracy is identical in all parts, if it is possible to draw or read to, say, 1 per cent. in one part of a curve, the same figure is true everywhere. On the other hand, in ordinary plotting the proportionate accuracy of quantities near the origin is very small, while at a great distance it becomes enormous. In order to assist in the process of sliding any curve about on a logarithmic chart so as to represent particular cases, special logarithmic scales may be ruled upon the sheet, having a suitable magnitude depending on the index which connects the result with the new variable, or what I have called scale lines may be employed. In illustrating the laws which connect the velocity and frequency of waves and ripples at the Royal Society soirée, I exhibited these lines, and showed how, in order to determine by inspection either the velocity or the frequency of waves and ripples of any wave-length on the surface of any liquid under any acceleration of gravity, a single curve and two scale lines are all that are needed. As by their use the logarithmic chart is made even more comprehensive than it is at present, I feel that no apology is needed for making use of the columns of NATURE to make them more widely known.

As is well known, the velocity of surface waves on a fluid depend both on gravity and on kinematic capillarity or capillarity divided by density. In the case of waves of large size, capillarity is of practically no account, and the velocity depends only on the acceleration of gravity. Since it depends on the square root of this acceleration, the line on the logarithmic chart that represents the velocity of waves of any size travelling under the influence of gravity alone is straight, and slopes up so as to rise one square for every two that it moves to the right, its tangent is

$= \frac{1}{2}$. On the other hand, since the velocity of waves travelling under the influence of capillarity alone is proportional to the square root of the wave shortness or reciprocal of the wave-length, the line that represents their velocity is straight also, but slopes the other way and to the same extent. Actually both causes are in operation, but except over a range of wave-length of about 1 to 100, the one influence so largely predominates that the other is negligible. In the diagram this is made evident on the velocity curve which consists of two straight branches joined by a curve, which runs into them and is rapidly indistinguishable from them. The dotted continuation of the branches shows what would be the velocities under the influence of either cause alone. Where the two lines cross, both gravity and capillarity have equal influence, and the two together



produce a minimum effect. The actual curve may be planted anywhere on the chart; but in the diagram it is so placed as to represent the facts with water for which $T/\rho = 81$ and with $g = 981 \cdot 1$. If other liquids are chosen, then, since the gravitational branch of the curve is unaffected, the curve, as a whole, must be made to slide along the gravity branch on the right until the left branch assumes its proper position. Similarly to represent the effect of changes of g, the curve must be made to slide along its capillary branch on the left until the gravity branch on the right assumes its proper position. The proper position in either case may be indicated by a special logarithmic scale ruled to half the scale adopted for the squares of the chart, and placed upon the chart with its length vertical and so that the branches of the curve cut each scale, one at 81 and the other at $981 \cdot 1$. The *scale line*, however, is much simpler, more convenient, and less confusing. In order to draw it, find a point in either branch of the curve where the velocity reading on the vertical scale of the chart is equal to the value of T/ρ for the left, or of g for the right branch. If within the limits of the paper the branch of the curve does not indicate a velocity, of which the value is T/ρ or g, as the case may be, take some whole power of 10 or $\frac{1}{10}$ as a factor. For instance, though $T/\rho = 81$ is within the limits of the left branch, $g = 981 \cdot 1$ is outside the paper on the right, therefore find on the right branch $g/10 = 98 \cdot 11$. Now, in order to find some other point on the scale line, imagine that each of these quantities is multiplied tenfold. The corresponding branch of each will be raised vertically $\sqrt{10}$, or half a square. The new line so drawn will at some point cut the vertical scale of the chart, in a line of which the value is ten times the reality, or is one square higher up than the first point. Mark this point, and join it to the first. The result is a *scale line* having the property that wherever it is cut by the corresponding branch of the curve the reading on the chart gives at once the value of T/ρ or of g, as the case may be, that is proper to the new position of the curve, and conversely in order to fix the place of the curve for any value of T/ρ or of g, it is merely necessary to find the desired values of these quantities on the scale lines, and then to shift the curve until its two branches or its two branches produced if necessary pass through the points on the scale lines having the values sought. If the effect of a variation of the constant upon the value indicated by the curve line is one of simple proportion, the scale line will be vertical. If its power is less than one, it will be

between the vertical and the slope of the curve; if more than one, it will slope the other way, if it is negative the slope will be less than that of the curve. In order to apply a general rule to all possible cases where both the index connecting x and y and the index connecting the result (y) with the variation of the constant may have any values whatever, it is merely necessary to find a point a upon the inclined straight line representing $y = ax$, at which y is equal to a, or to that part of a which may assume various values. At any distance above it rule a horizontal line. Where the horizontal line cuts the inclined line, write the figure 0; where it cuts the vertical through the point a, write the figure $+1$. Then complete a scale of equal parts on the horizontal line extending to $+\infty$ and $-\infty$. Lines drawn through the original point a and any point q on this scale will be scale lines corresponding to the case where the result depends upon the qth power of the constant as well as upon the bth power of x.

The frequency curve placed upon the same chart has two branches inclined at $\tan^{-1} - \frac{3}{2}$ and $\tan^{-1} - \frac{1}{2}$, joined by a curve such that not only on the straight branches, but at every point, the algebraical difference of the tangent of its inclination and that of the velocity curve for the same value of x the wave-length is equal to unity. The left-hand branch of the frequency curve supplies another example of the rule given above for drawing a scale line: for, while its tangent is $-\frac{3}{2}$, that of the scale line is -3.

It is evident that the curve may be conveniently drawn upon tracing-paper, which may then be moved about, but always keeping the inclinations unchanged until the branches pass through the desired points upon the scale lines. The numerical relations for the new constants may then be read at once.

I have thought it best to explain the method by the use of a concrete example. Of course it is not limited to the case of ripples and waves, but may be applied very widely.

By way of illustrating how to change from one system of units to another, I have drawn a pair of double-ended arrows in the middle of the chart, which show the magnitude and direction of the movement of each of the curved lines with its straight dotted continuations, which will be necessary in order to read the results in inches instead of in centimetres. The one relating to velocities is inclined at 45°, as both the velocity and wave-length are equally changed in the ratio of 2·54 : 1, or 1 : ·3937. On the other hand, the frequency being a mere number is not affected, except in so far as the wave-length will be expressed by a different number. Hence the direction of sliding is here horizontal and the same in amount as either component of the other. The scale lines must then be put in parallel to their former directions, and running through points for which the vertical scale reading has the numerical value of the constant according to the system of units chosen.

C. V. BOYS.

[*Note.* The numerical values represented by the vertical and horizontal lines in each square in the diagram are 1, 1·5, 2, 2·5, 3, 3·5, 4, 4·5, 5, 5·5, 6, 6·5, 7, 7·5, 8, 9, 10. The number of lines in the Human sheets is five times as great, but they are drawn in three degrees of darkness to distinguish them.—C. V. B.]

NOTES.

A REPRESENTATIVE meeting of friends and admirers of the late Mr. Huxley was held on Thursday afternoon, at the rooms of the Royal Society, under the chairmanship of Lord Kelvin, F.R.S., to consider what steps should be taken to initiate a national memorial. It was determined to call a general public meeting after the autumn recess, and, in the meantime, to form a general committee. Sir John Lubbock (15 Lombard-street) has consented to act as treasurer, and Prof. G. B. Howes (Royal College of Science, South Kensington) as secretary to the provisional committee.

WE notice, also, that it is proposed to establish a memorial to commemorate the connection of Huxley with the Charing Cross Hospital Medical School. At a meeting held at the School on Tuesday, the following resolution was passed: "That the memorial shall take the form of a Huxley scholarship and medal to be awarded annually at the Charing Cross Hospital Medical School, and that if funds permit an annual public lecture at the Charing Cross Medical School dealing with recent advances in science, and their bearing upon medicine shall be instituted."

WE understand that a large majority of those Fellows of the Royal Society who have expressed an opinion on the matter, being in favour of retaining the present quarto form of the *Philosophical Transactions*, the President and Council have decided to retain that form. As stated in a circular recently addressed to Fellows, the President and Council, finding that the majority of those expressing their opinion were in favour of a royal octavo form for the *Proceedings*, have decided to adopt that form. The change will probably be made at the beginning of next year.

SEVERAL new instances of generous gifts for the advancement of scientific knowledge are reported in *Science*. Mr. Archibald, President of the Trustees of Syracuse University, has offered to be one of six subscribers for funds to build a hall of science costing about £30,000. The University has also been offered £2000 and £20,000 towards a new medical college. Another American institution which has benefited by the epidemic of generosity which has lately prevailed in the United States is the Johns Hopkins University, which has received from Mrs. Williams a sum of money sufficient to establish a lectureship in geology in memory of the late Prof. George H. Williams. Sir Archibald Geikie has been invited to be first lecturer.

THE sum of £50,000 required for the New York Botanic Garden has been contributed by twenty-two donors. Subscriptions of £5000 were given by each of the following:—Mr. J. P. Morgan, Columbia College, Mr. Andrew Carnegie, Mr. C. Vanderbilt, Mr. J. D. Rockefeller, Mr. D. O. Mills, Judge A. Brown. Mr. Wm. E. Dodge, Mr. J. A. Scrymser, and Mr. Wm. C. Schermerhorn each gave £2000, and there were eight subscribers of £1000 each. The act of incorporation required that this amount be collected for an endowment. The city must now raise £100,000 by bonds for building purposes, and provide 250 acres of land in Bronx Park. This part of the agreement will probably soon be carried out, so New York may look to possessing shortly a botanic garden of the first order. Writing with reference to the prospect in *Science* of July 5, Prof. G. L. Goodall, of Harvard University, remarks: "To Columbia College and the other educational institutions of New York and vicinity, this new appliance for instruction will mean indeed a great deal. To all the citizens who are to take advantage of the opportunities for instruction which the garden will afford, Bronx Park will be a constant delight. But far beyond these limits, wide as they are, the garden will exert a profound and beneficial influence. Other cities will surely be stimulated by this noble movement and enrich their park systems with an educational aid of the greatest value. Formerly botanic gardens, attached even in a remote manner to educational institutions, were largely used for the cultivation of medicinal plants, and for the reception of species from distant lands. Of course, this use, although its importance is now relatively less than ever before, will still long continue to be a factor in the direction of activities. But here and there new phases of plant

relations are being displayed in the greater gardens, and with the most gratifying results. Geographical questions are asked and answered by skilful grouping of species, and in the most attractive way. The bearing of climate on the structure, habit, and possibilities of plants is made prominent in an interesting fashion. The capabilities of useful plants and the extension of their range of usefulness comprise another phase of illustration which always sets visitors to thinking. Beyond and, we may say, above these questions, which are pretty strictly utilitarian, there comes nowadays another class of illustrations which are of the highest educational value in a community, namely, the biological features which are invested with such important relations to all departments of intellectual activity."

We regret to announce the death of Prof. F. Tietjen, for many years past Director of the Recheninstitut of the Berlin Observatory, and editor of the *Berliner Astronomisches Jahrbuch*; also of Prof. G. F. W. Spörer, of the Potsdam Observatory, well known amongst astronomers for his solar observations.

A statue to Boussingault was unveiled at the Paris Conservatoire des Arts et Métiers last week. The French Minister of Agriculture, who presided at the inauguration, pointed out how very largely Boussingault's work had benefited agriculture. The funds for the erection of the monument were raised by public subscription, through a Committee of which M. Schloesing was the president.

A few days ago, the Municipal Council of Paris, and the General Council of the Seine, presented Dr. E. Roux, who has devoted so much attention to the anti-toxic serum treatment of diphtheria, with two gold medals struck in his honour. M. Pasteur was unable to be present on account of ill-health, but he sent a letter in which he expressed his great gratification at the way in which the municipality were publicly expressing their appreciation of the work of his pupil and collaborator.

Sir William H. Flower, K.C.B., has been elected a Correspondant of the Paris Academy of Sciences; and Prof. Cohn has been elected to succeed the late Marquis de Saporta, as Correspondant in the Section of Botany.

The death is announced of Dr. Hermann Knoblauch, President of the Kaiserliche Leopoldinisch-Carolinische Akademie of Halle. He died in the seventy-sixth year of his age on June 30th.

Dr. Fabian Franklin, Professor of Mathematics in the Johns Hopkins University, has resigned his position in order to take up editorial work on the *Baltimore News*.

M. Paul Sintenis has returned from Turkish Armenia with large collections of rare plants.

Sir Edward Lawson will distribute the prizes to the students of the Charing Cross Hospital Medical School this afternoon, at 4 o'clock. Next Thursday evening, the distribution of prizes to the students of the Dental Hospital of London will be made by Sir William MacCormac, at a conversazione to be held in the Royal Institute Galleries, Princes Hall, Piccadilly.

The University of Chicago has decided to add Terrestrial Physics to the subjects taught in the Physical Department under Prof. Michelson, says the *American Meteorological Journal*. Dr. L. A. Bauer has just commenced courses in terrestrial magnetism, thermodynamics of the atmosphere, and dynamic meteorology. This step marks a new era in the development of the study of meteorology in the United States.

Prof. F. Omori, of the Seismological Institute of Tokio, contributes an interesting paper on the velocity of earthquake-waves to the *Bollettino* of the new Italian Seismological Society (vol. i., 1895, pp. 52–60). The chief value of his investigation lies in the fact that the distances traversed are generally short and the times exceedingly accurate, so that we thus obtain some idea of the surface-velocity in the neighbourhood of the epicentre. The mean velocity for twenty-five earthquakes (1891–94) is found to be 2·04 km. per second. Prof. Omori also shows that for earthquakes originating in the same region, the velocity is practically constant, whatever be the intensity of the initial disturbance or the distance of the place of observation from the centre.

The prizes and medals of the Paris Société d'Encouragement have just been awarded. The prize of twelve thousand francs (£480), awarded every six years to the author of the most useful discovery to French industry, has been given to Prof. Lippmann, for his method of photographing colours. Among the other awards we notice the following: Prize of 2000 francs to M. F. Osmond for his works on the microscopic analysis of steel, of which an account is given in the May *Bulletin* of the Society; 500 francs to M. Garçon for his work on "La Pratique du teinturier"; 1000 francs to M. Ch. Tellier, 500 to M. Lacroix, 500 to M. Maignen, and 500 to M. Schlumberger, for the purification of potable waters; 500 francs each to M. Lartigue and M. Roux for their investigations in connection with the electrical installations; 1000 francs to M. Guerrier, 500 francs to M. Allard, and 500 francs to M. Martin for their agricultural studies. The grand gold medal, awarded every six years for works which have exercised the greatest influence upon the progress of French industry during the preceding six years, has been given to the Comité de l'Afrique française for their great services to African colonisation.

The current number of the *Annales de l'Institut Pasteur* contains an official account of the antirabic inoculations carried out at the Pasteur Institute in Paris during the past year. From this it appears that 1387 persons were treated, out of which seven died subsequently. On comparing the statistics for last year with those compiled for 1893, we find that although the total number of admissions fell short last year by 261 of the figure reached in the previous year, yet England's contribution in the shape of patients rose from 23 in 1893 to as many as 128 in 1894. Thus, in spite of the broadcast circulation of a vast amount of sentimental opposition to the carrying out of Pasteur's antirabic treatment in this country, we appear to be developing an increasing desire to avail ourselves of the benefits to be derived from its use across the Channel! In all, 226 foreigners were treated in the Institute last year; Spain and Greece each sending 26; Belgium, 16; Turkey, 7; Russia and Egypt, 1 each; and Holland, 2; whilst under the heading "Indes Anglaises" we find 19 as compared with 14 last year.

In connection with the questions lately raised as to the relation of spectra to molecular structure, it is interesting to recall a paper by Prof. Eder and and Mr. Valenta, communicated to the Vienna Academy a year ago. Mr. J. S. Ames summarises the paper in the May *Astrophysical Journal* as follows:—"The paper deals with the different spectra of mercury. Observations on the arc and spark-spectra and on the ordinary Geissler tube discharge showed that all three were alike, the most prominent lines in one spectrum being also the most prominent in the others. But two entirely new spectra were discovered. If mercury vapour is distilling at a low pressure through a capillary tube, and if a spark be passed through it, spectra are observed which are quite distinct from the ordinary one. If there is a large number of Leyden jars in circuit, the spectrum consists of an *immense* number of fine, sharp lines; but if there are no jars in circuit, the spectrum is entirely changed; it becomes a series of bands

whose edges are towards the red. One spectrum is just as complete as the other, neither one being a development of the other. The band spectrum corresponds to a trifle lower temperature than the new line spectrum; but it is difficult to see how complexity of molecular structure can account for the difference between the two spectra in the case of mercury, whose vapour is monatomic. This has, of course, a most important bearing on the theory of band and line spectra, and seems to decide definitely against some of the present ideas concerning them."

THE current number of *Wiedemann's Annalen* contains a paper by Herr J. E. Myers on the influence of gases dissolved in the electrolyte of a silver voltameter on the weight of deposited silver. The author finds, as has previously been shown by Schuster and Crossley, that if the same current is sent through two voltameters containing neutral solutions of silver nitrate of the same strength and at the same temperature, one voltameter being in a vacuum and the other in air, then the weight of the silver deposited in the vacuum voltameter is, for a solution containing from 20 to 40 per cent. of silver nitrate, about 0·1 per cent. greater than that of the silver deposited in the other voltameter. For a 5 per cent. solution, the difference is somewhat smaller. If the solution is saturated with carbon dioxide the deposit is about 0·055 per cent. lighter than when the solution is saturated with air. With nitrogen, however, the deposit is about 0·05 per cent. heavier than with air. The electrical resistance of a 5 per cent. solution saturated with air is practically the same as that of the same solution in a vacuum. With a current of more than 0·25 ampere, it is found that in vacuum an evolution of gas takes place at the anode. The author has also examined the grey deposit which is formed on the anode, and finds that it consists of pure silver oxide.

THE results of some observations on declination made by M. Ch. Lagrange, which, if unaffected by some unsuspected error, are most unexpected, are given in a recent number of the *Comptes rendus* (June 17, 1895). During the last three years the author has been making observations of declination at the Uccle Observatory at Brussels, using for this purpose magnets having very different magnetic moments. He finds that systematic differences occur in the values obtained, but what is most astonishing is that diminution, within certain limits, of the magnetic moment of the magnet causes an amplification of the observed changes in declination. In one set of observations, lasting for six months, one of the magnets consisted of the almost astatic magnetic system taken from a galvanometer. By comparing the readings obtained with this system of magnets with those obtained on the self-registering magnetometers, it was found that the amplitude of the movements of the galvanometer needle was from fifteen to twenty-five times as great as that of the magnetometer needle. Another set of observations have been made with a large steel magnet, only feebly magnetised, however, so that its magnetic moment was only about [illegible] of that of the magnet of the magnetograph. This magnet was suspended by a fine platinum wire, and here again the amplitude of movement of the feebly magnetised bar was [illegible] than that of the more strongly magnetised one.

WE have received *Bulletins* Nos. 119-124 of the Michigan Agricultural Experiment Station, dealing with a variety of subjects of [illegible] interest. With regard to the troublesome [illegible] rot, which is often the cause of serious loss, it is stated that spraying with Bordeaux mixture is efficacious. [illegible] when the tomatoes had grown to the size of [illegible] the plants were given a thorough spraying, and [illegible] after the application was repeated. Very little rot [illegible] on the sprayed plants, whilst on those which were purposely left unsprayed many diseased fruits were to be seen. In the summary of results of experiments with potatoes, it is said that potatoes deteriorate rapidly under ordinary cultivation, and it is necessary to frequently change seed in order to keep them in their pristine purity and excellence. We need go no farther than Ireland, with its worn-out variety of the Champion potato, for a case in point. As a treatment for apple-scab (*Fusicladium dendriticum*, Fckl.) it is recommended to thoroughly spray the trees, before growth begins in spring, with copper sulphate solution. This should be followed with an application of Bordeaux mixture as soon as the blossoms have fallen. In a wet season two or three more dressings will be necessary to produce the best results. The addition of Paris green to the second and third applications will keep the codlin-moth and the canker-worm in check. A caution is given never to spray with arsenites when fruit-trees are in bloom, or the bees will be killed.

AN attempt at a partial restoration of the geography of the world in Cretaceous times is made by Dr. F. Kossmat, of Vienna, in the May number of the *Records* of the Indian Geological Survey. He recognises the broad distinction of Atlantic and Pacific faunal provinces in Cretaceous times, a distinction very marked in the northern hemisphere, but disappearing to the south of the then existing Indo-African continent. The Cretaceous beds of Southern India form the clearest link between the two; combining in their fauna the typical Pacific forms with others characteristic of Central Europe. Their connection with the latter area was a roundabout one, through Natal, Angola, and the Atlantic, by which they are also linked to the Cenomanian and Danian deposits of Brazil. The fauna of Northern India is quite distinct, and must be regarded as inhabiting the easterly termination of the Mediterranean province, one which was an almost isolated area, though to the westward, in the Gosau beds and those of Southern France, we can see evidence of a connection with the Atlantic. Further west a similar fauna is found in the Antilles, and extends even into the Pacific region in Peru. The fauna of North America shows close affinities with that of Europe, and less marked relations to that of Southern India, while it stands sharply contrasted with that of the Pacific side of the continent. The upper Cretaceous beds of Atlantic facies are found, however, to extend into British Columbia and Queen Charlotte's Islands, and there rest upon lower Cretaceous beds of Pacific facies. The American continent must thus have existed as two great insular masses forming a barrier between the two great marine provinces, broken across by two arms of the sea. The author purposes constructing a chart to embody these conclusions.

THAT quite a considerable number of bacteria exist which will only grow at such high temperatures as lie between 50° and 70° C., was first shown by Globig; but his investigations only succeeded in demonstrating them in the superficial layers of soil. Now, however, we know that such bacteria are to be found in river water and mud, in fæces, and at considerable depths in the soil. Quite recently Dr. Lydia Rabinowitsch has made extensive researches in Dr. R. Koch's laboratory on these so-called thermophilic bacteria, and their distribution appears to be much wider than was at first supposed. Thus Dr. Rabinowitsch has found them abundantly present in surface soil collected from various parts of Berlin and other places in Germany; they were also discovered in freshly-fallen snow, indicating their probable presence in the air, and large numbers were obtained from river Spree water, although they were not found in the Berlin water supply; they were also isolated from excrementitious matter derived from horses, cows, goats, dogs, rabbits, ducks, parrots, some fish and other cold-blooded animals, such as the frog and python. These bacteria are also

present in large numbers in the mouth and all along the intestinal tract of man. Cow's milk contains them, and they are not destroyed even when the latter is vigorously boiled. The most favourable temperature for the growth of these thermophilic bacilli lies between 60° and 70° C., but they may be induced to grow also between 34° and 44° C. It would be interesting to learn what part is played by these bacteria in nature, and it is to be hoped that Dr. Rabinowitsch will continue these investigations, and instruct us as to these functions of thermophilic bacteria.

DR. J. HANN has sent us a copy of his paper on the conditions of atmospheric electricity on the summit of the Sonnblick mountain, deduced from the records of an improved registering hair hygrometer by Richard, which had been adjusted and tested at the Central Meteorological Office in Vienna. The discussion is one of much importance, and the subject is treated by Dr. Hann in a very thorough manner; but the space at our disposal will only allow us to notice briefly some of the general results. The yearly range of relative humidity on the mountain is the reverse of what it is over the plains; the minimum, or greatest dryness, occurs in winter, and the maximum in spring and summer. This much was known from observations at Alpine stations, but at these the uncertainty of the behaviour of the hygrometers in low temperatures made the results doubtful. Temperature and vapour pressure on the Sonnblick run in nearly parallel curves, each degree of difference of temperature corresponds to a change of tension of vapour in the same direction. With regard to the daily range, it is found that in all, except the three winter months, there is low relative humidity in the morning and a great humidity during the evening and night. In winter, however, the case is very different; from about 6h. p.m. to 7h. a.m. the relative humidity remains below the mean, and from 9h. a.m. to 5h. p.m. it is above the mean. The daily range of absolute humidity (vapour tension) is nearly the same in all seasons of the year; the minimum occurs early in the morning, and the maximum in the afternoon. The most remarkable feature in the daily range of relative humidity is that on very clear and warm days, long before the rise of the sun has any effect, the humidity falls below the mean value on the Sonnblick, and by about 6h. in the morning, it has fallen nearly 7 per cent. below the daily mean. This important fact seems to show that the relative dryness of the forenoon on mountains is due to a descending movement of the atmosphere, caused by the winds blowing from the mountains to the valleys during night-time, and thus cooling the sides of the mountains.

THE July *Journal* of the Chemical Society contains the paper on "Helium, a Constituent of certain Minerals," by Prof. W. Ramsay, Dr. J. Norman Collie, and Mr. M. Travers, read before the Society at the last meeting. There are also fifteen other papers read before the Society, and 138 pages of abstracts of chemical papers published in other journals.

WITH the current number, the *Medical Magazine* enters upon its fourth year of issue. The magazine is always readable, not only by members of the medical profession, but by the laity, and the papers which it publishes on medical history and literature are invariably of general, as well as technical, interest. We notice among the articles in the number before us, one on "Mountain Sickness," by Dr. H. Kronecker; and another on "Immunity," by Dr. J. G. Sinclair Coghill.

UNDER the title *Beiträge zur wissenschaftlichen Botanik* a new contribution to general botanical literature is announced, to be edited by Dr. M. Fünfstück, and published by Nägele, of Stuttgart. The first number, which is already published, contains papers on the physiology of woody plants, by Lutz; on the action of "Bordeaux-brühe" and its constituents on *Spirogyra longata* and on the uredespores of *Puccinia coronata*; and on the oily excretions of calcareous lichens, by the editor.

THE report for 1894 of the American Museum of Natural History shows that a number of valuable specimens were added to the collections last year. The new wing, for the building and equipment of which 550,000 dollars (£110.000) were voted in 1893 and 1894, is approaching completion, and is expected to be opened to the public in the autumn. Since the preparation of the report, the Legislature has given power to the authorities of New York City to appropriate £100,000 for a further enlargement of the museum, and for an increased grant of £4000 annually, for maintenance. The erection and equipment of another wing to the museum will provide the facilities for carrying out the plans of the Trustees for the establishment of a great department of Anthropology.

THE report of the Trustees of the South African Museum, for the year 1894, has been received. As the staff of the museum does not include collectors, it is gratifying to learn that nearly seven thousand specimens were presented by private collectors during last year. That the museum is appreciated is evidenced by the fact that the number of visitors in 1894 was nearly twenty-six thousand. The Curator, Mr. R. Trimen, has completed the manuscript of descriptions of new Lepidoptera from Mashonaland, which will be published at the beginning of the year. He has also begun the incorporation of the tropical African insects of this order in the South African collection, adopting the 16° of latitude S. as the South African limit. The staff has been increased by the appointment of Dr. G. S. Corstorphine as assistant in the department of geology and mineralogy. A report by him, on the existing collection of that department as at present exhibited, is appended to the report of the Trustees.

THE additions to the Zoological Society's Gardens during the past week include a Campbelli Monkey (*Cercopithecus campbelli*) from West Africa, presented by Miss C. Thompson; a Yellow-billed Sheathbill (*Chionis alba*), captured at sea, presented by Captain Plunket; four Common Chameleons (*Chamæleon vulgaris*) from Egypt, presented by Mr. J. C. Mitchell; a Sharp-nosed Crocodile (*Crocodilus acutus*) from Columbia, presented by Mr. James G. Green; a Royal Python (*Python regius*) from West Africa, presented by Colonel Frederick Cardew; an Alexandra Parrakeet (*Polytelis alexandræ*) from Australia, six Grey Francolins (*Francolinus ponticerianus*) from Mombassa, a Black Tortoise (*Testudo carbonaria*) from South America, deposited; five Fennec Foxes (*Canis cerdo*), two Variegated Jackals (*Canis variegatus*), two Libyan Zorillas (*Ictonyx lybica*), two Egyptian Cats (*Felis chaus*), three Dorcas Gazelles (*Gazella Dorcas*), four White Pelicans (*Pelecanus onocrotalus*), a Grey Monitor (*Varanus griseus*), from Cairo, received in exchange; a Wapiti Deer (*Cervus canadensis*), two Short-headed Phalangers (*Belideus breviceps*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE NEW MADRAS OBSERVATORY.—Prof. Michie Smith, the successor of Mr. Pogson at Madras, has lately made known a few particulars relating to the new Solar Physics Observatory which is to be erected in India. The funds have been voted by the Indian Government, and the site selected is in the Palani Hills at Kodaikanal, 300 miles south of Madras. The daily work of photographing the sun, which is now carried on for the Solar Physics Committee at Dehra Dûn by the officers of the Indian Trigonometrical Survey, will form part of the routine work of the new observatory. It is also proposed to undertake a systematic spectroscopic examination of the sun, but the details of this portion of the programme have not yet been finally determined upon. The climate of Kodaikanal seems to be almost all that can be desired for astronomical purposes. The mean daily temperature varies from 54°·1 C. in December to 62°·2 C. in May, while the rainfall is about 47½ inches. From March to December in the year in which observations were

specially made, the bright sunshine amounted to 1634 hours; the morning is usually bright until about eleven o'clock, then clouds come up and continue until about four o'clock; by six o'clock the sky is generally cloudless. Except during the north-east monsoon, a night which is wholly cloudy is almost unknown. Under these highly advantageous conditions, there is every prospect that the establishment of this observatory will result in a great gain to astronomy, especially in the department of solar physics.

Star Catalogues.—An admirable *résumé* of the history of star cataloguing, from the pen of Mdlle. Klumpke, the gifted directress of the *Bureau des Mésures* of the Paris Observatory, appears in the current number of the *Bulletin* of the Astronomical Society of France. From an instrumental point of view three great epochs may be recognised, each marked by some important discovery. The first epoch is that in which the line of vision is defined by hollow cylinders or by an alidade, and extends from the time of Hipparchus to that of Hevelius; it comprises the catalogues of Hipparchus, Ptolemy, Ulugh-Beigh, and Tycho Brahe. The catalogue of Hevelius, though drawn up from observations with the naked eye, marks a transition period, as he took advantage of the application of the pendulum to the regulation of clocks.

The second epoch is marked by the application of the telescope for accurate sighting of the heavenly bodies, and the employment of the sidereal clock. This period commenced with Flamsteed, and extends even to the present time. In the third epoch the photographic plate replaces the eye. Enthusiasm for this method of cataloguing the stars commenced with the fine results obtained by the Henrys, but it should not be forgotten that as far back as 1865, Rutherford obtained photographs of stars down to the ninth magnitude, and that he clearly foresaw the advantages to be derived from the photographic method. All the world knows now that a great photographic chart of the heavens, initiated by the late Admiral Mouchez, is in course of construction, eighteen observatories participating in the gigantic undertaking. Mdlle. Klumpke estimates that this international catalogue will contain upwards of three millions of stars.

The photographic method, however, does not yet appear to be without imperfections, as the impressions on the negatives are not certainly permanent. In a communication to the editor of the *Observatory*, Dr. Isaac Roberts gives some figures relating to the disappearance of the smaller images in the course of years; in one negative no less than 130 out of 364 star images had disappeared in nine and a quarter years. Hence it is important that as short a time as possible should elapse between the taking of a photograph and its reduction, or, better still, its manifolding by some carbon process.

THE PLACE OF ARGON AMONG THE ELEMENTS.

The position of argon in a classification of the elements depending on atomic weights has been recently defined by C. J. Reed (*Journal of the Franklin Institute*, July). The elements are assigned positions on a plane determined by abscissæ proportional to their atomic weights and ordinates proportional to their valency. Oxygen is assumed to have an electronegative valency 2, and the valency of other elements is referred to this as standard; electro-positive valency is measured upwards, electro-negative downwards from the zero-axis. Under these conditions most of the elements fall on a peculiar series of double, equi-distant, parallel straight lines, connecting elements in order of their atomic weights and separated alternately by distances corresponding to one and sixteen units of atomic weight respectively.

If the plane be now folded into a cylinder with axis parallel to the abscissæ and a circumference of eight units of valency, it is found that the upper and lower parts of the connecting lines coincide; the whole of these lines then form a parallel pair of spirals on the surface of the cylinder, and valency in angular measure becomes directly proportional to atomic weight.

The regularity with which the elements of lower atomic weight fall alternately on each of the parallel spirals is very striking, but this regularity is not maintained among elements of high atomic weight, notable deviation occurring with most of the elements of which the atomic weight ranges from 100 to 130. The axis of atomic weights represents the valency + 0 or + 8 and is cut by the double spiral in fifteen points. There should then be a group of fifteen elements having a valency of zero or eight, and their atomic weights should be, respectively, 4, 20, 36, 52, 68, 84, 100, 116, 132, 148, 164, 180, 196, 212, and 228. All the known elements appear to be grouped together on certain regions of the surface of the cylinder, other parts remaining comparatively bare. The only members of this family to be expected to occur in terrestrial matter will be those in the inhabited regions of the cylinder surface. The hypothetical elements having atomic weights 20, 36, 84, and 132 are the most necessary from this point of view.

It seems reasonable to suppose from the peculiar position of these elements on the border-line between electro-negative and electro-positive valencies, that they should be more strongly electro-negative than the corresponding members of the sulphur group, and should nevertheless be without valency (or octads). They should, in general, be more volatile than the corresponding members of the sulphur group. As electro-negative valency diminishes in any group with increase of atomic weight, the element 196, if it exists, cannot be expected to be electro-negative. This element should be a volatile metal, heavier and scarcer than gold, and capable of easier reduction to the metallic state; it should be capable of forming an oxide RO_4 or a salt K_2RO_5. The volatile metal osmium agrees with the requirements of this element very closely. Similarly, ruthenium may possibly be the element 100.

Finally, argon falls naturally into the place of element 20, and possesses, so far as is known, the properties to be expected of this element in position 20 in the new group. Argon and element 36 should be comparatively abundant in nature, while 84 and 132 should be scarce, but not more rare than selenium and tellurium.

On Mr. Reed's system, argon should be element 36 if it be monatomic as now believed, and not 20 as he assumes; the actual atomic weight found, 39·9, would then indicate the possibility of the presence in argon of some small quantity of element 84 or element 132. It is remarkable also that, if helium has the atomic weight 4, it falls naturally in this group, and that its atomic weight deduced from the observed density is somewhat greater than this number. If this difference should be due to the presence of some small quantity of element 84, then the spectroscopic evidence leading to the conclusion that argon and helium contain a common constituent would be explained.

POCKET GOPHERS OF THE UNITED STATES.

In *Bulletin* No. 5 of the U.S. Department of Agriculture, Mr. Vernon Bailey gives an account of the habits and life-history of the Pocket Gophers of the United States, which contains a number of interesting facts and observations derived from various sources. These curious little rodents live underground in burrows which they tunnel in the soil. When working their way through the earth, they use the upper incisors as a pick to loosen the ground, while the fore-feet are armed with strong curved claws for digging. When a sufficient quantity of soil has accumulated behind an animal, he turns in the burrow and pushes it out in front until an opening in the tunnel is reached; the earth is here discharged, and forms a hillock similar to the hills thrown up by moles. Gopher burrows are extended and added to year by year, and the course is marked by the hills of soil brought up to the surface. Gophers do not hibernate, as has been commonly supposed, but work steadily throughout the winter. They do a great deal of good in mixing the soil, and in this way are probably most useful on poor or uncultivated ground. But, on the other hand, in agricultural districts the animals are highly injurious: they devour potatoes and other tubers and roots in large quantities, as well as corn, wheat, and other farm crops; and they destroy great numbers of fruit trees by gnawing off the roots. Gopher burrows also often do a great deal of damage in meadows or on the banks of artificial water-courses. So great is the harm done by Gophers, that in many districts bounties have been offered for their capture. One of the most striking features of Pocket Gophers is their possession of cheek pouches opening outside the mouth. It is commonly supposed that these pouches are used for carrying earth out of the burrows; but Mr. Bailey's investigations lead him unhesitatingly to the conclusion that this view is erroneous; they are used only for carrying food pieces of

potato and roots, leaves, &c.—to be eaten at ease in the seclusion of the animals' burrows, or to be stored up for use in the winter. The food is passed into the pouches by the fore-feet; and the animals empty their pockets by pressing the sides of the head with the fore-feet from behind forwards, so that the contents fall out in front of them. In disposition Gophers are very fierce; and on the rare occasions on which they wander from their holes, frequently attack passers-by without any provocation. They are not very prolific animals, as is commonly stated, for only one litter of two or three young is produced in a year; but, although their rate of increase is slow, their mode of life protects them from many enemies which attack squirrels, mice, and many other rodents. The Pocket Gophers of the United States belong to three genera, *Geomys*, *Cratogeomys*, and *Thomomys*: Mr. Bailey gives two charts illustrating the distribution of these different genera and their constituent species.

COLOUR PHOTOGRAPHY.

An important paper on the theory of colour photography is contributed to No. 6 of *Wiedemann's Annalen*, by Herr Otto Wiener. The paper deals with the methods of attacking this problem which are based, not upon the photography of the different constituents of coloured light and their subsequent recognition—like Mr. Ives's heliochromy and similar processes—but upon the direct production of colour by the influence of light upon certain chemical substances. The most recent, and in a way the most successful of these methods is that due to Lippmann, and the question raised by Herr Wiener is whether the old processes invented by Becquerel, Seebeck, and Poitevin are based upon interference colours like Lippmann's, or upon "body colours," *i.e.* colours produced by partial absorption of the incident light. That Lippmann's colours are due to interference may be very simply proved by breathing upon a plate with a photograph of the spectrum, when the colours quickly wander towards the violet end, this result being due to an increase in the distance between the nodal layers. This experiment cannot be applied to a spectrum photographed by Becquerel's method. But Herr Wiener succeeded, by a simple and ingenious contrivance, altering the path of the rays through the coloured film by placing a rectangular prism on the plate, with its hypothenuse surface in contact with the spectrum. This experiment had the startling result that that part of the spectrum covered by the prism appeared strongly displaced towards the red. Hence Zenker's theory of Becquerel's process, enunciated in 1868, which ascribed the colours to interference, is substantiated. Instead of Becquerel's homogeneous sheet of silver chloride containing subchloride, Seebeck used the powder, and Poitevin mounted the salt on paper. In these two processes the effect described is not observed. Hence these colours are body colours in these two cases. The production of these body colours is a very mysterious process, but the author hopes that here will eventually be found a satisfactory solution of the problem. To account for the production of these colours he advances a remarkable theory which has a well-known analogy in comparative physiology. Given a collection of compounds of silver chloride and subchloride of indefinite proportions, such as those which Mr. Carey Lea calls by the collective name of "photochloride," we must suppose according to the modern kinetic theories that they are undergoing a rapid series of successive modifications. When the red combination happens to be exposed to red light, it reflects it without absorption, and will therefore no longer be affected or changed by it. Similarly for the other cases. This is another process of "adaptation." The author describes some experiments which prove that this is the true explanation, and points out the importance of this view, not only for colour photography, but for the production of colours in the animal world.

THE SLATE MINES OF MERIONETHSHIRE.[1]

An official Blue Book drawn up by a Departmental Committee appointed by Mr. Asquith, and referring to the dangers of slate quarrying in Merionethshire, has recently appeared. After a brief account of the mode of occurrence, the method of getting the slate by true mining operations is described, and the principal causes of accidents are enumerated and explained. Judging by the statistics of the last nineteen years, the underground worker in Merionethshire is exposed to greater risks than the average collier; some 40 per cent. of the deaths are caused by falls of rock, a fact which causes no surprise when one considers the conditions under which the slate-getters carry on their daily work in huge chambers, the roofs and sides of which cannot be examined without rigging up lofty ladders.

An interesting table of death-rates shows that the Merionethshire slate quarrymen are better off as regards the safety of their occupation than many other classes of workmen, such as navvies, railway servants, and sailors.

The medical evidence, especially that of Dr. Richard Jones, is very complete, and we learn that some of the ills of the Merionethshire quarrymen are practically of their own making. Judging by the report and the evidence upon which it is based, the men are not cleanly in their ways, and if their sober habits lead them to ruin their digestions by stewed tea, it becomes a question whether their so-called, but incomplete, temperance is an unmixed benefit.

For preventing accidents, the Committee make several useful suggestions; one of the most important is their advocacy of "channelling machines" or "groove cutters," for assisting in getting the slate, instead of violently wrenching off the blocks by blasting.

The value of the report is enhanced by some useful appendices, a copious index of the evidence, and several woodcuts and plates. The plates are noteworthy as being the first instances of reproductions of photographs in a Blue Book by the half-tone process. Five of the eight photographs were taken underground by magnesium light; the two best, which represent ladders set up in underground chambers, are the work of Mr. Burrow, of Camborne, already well known by his successful pictures of Cornish mines.

The report is signed by Mr. Le Neve Foster, the Inspector of Mines of the district, Mr. J. E. Greaves, the owner of one of the largest slate mines, Mr. E. P. Jones and Mr. J. J. Evans, both quarry managers of wide experience, and Mr. J. Jenkins, President of the Quarrymen's Union. The opinions of a practical Committee of this kind are entitled to consideration, and it will be interesting to note how far their suggestions are carried out, and how far they attain their object, viz. the increased safety and general well-being of the Merionethshire quarrymen.

[1] Report of the Departmental Committee upon Merionethshire Slate Mines, with Appendices. Presented to both Houses of Parliament by command of Her Majesty, 1895.

THE RELATION OF BIOLOGY TO GEOLOGICAL INVESTIGATION.[1]

II.

THE RELATIVE CHRONOLOGICAL VALUE OF FOSSIL REMAINS.

Rejecting the idea of special endowment held by early geologists, we must consider the relative chronological value of fossil remains with reference to the natural laws which have produced their characteristics and governed the various conditions of their origin. Much may profitably be said concerning the comparative chronological value of the different genera, families, &c., belonging to one and the same class of any branch of either the animal or vegetable kingdom, or to different classes; but I propose to discuss only the broader relations to one another of the more general kinds of fossil remains. These discussions will relate to the time-range of each of those general kinds, the various conditions under which they have been preserved, the various conditions of habitat of the animals and plants which they represent, the relative rate of evolutional development of the different kinds and their differences of reciprocal relation to one another.

No fact in historical geology is more conspicuous than that of the great differences in time range of the various kinds of organic forms, some of them having ranged through the whole of the time represented by the geological scale, while others, and among them some of the biologically most important kinds, ranged through only a comparatively small part of it.

A special grouping of the different kinds of fossil remains is more appropriate for these discussions than is a strictly systematic one, and I have therefore adopted the following: (*a*) marine invertebrates, (*b*) non-marine and land invertebrates, (*c*) fishes, (*d*) batrachians and reptiles, (*e*) birds, (*f*) mammals, and

[1] By Charles A. White. Abstract of a series of eight essays published in the Report of the United States National Museum. (Continued from p. 261.)

(G) land plants. For convenience of reference, our present knowledge of the time-range of these kinds may be presented in tabular form. The accompanying illustration, representing the whole of geological time by its height, indicates in a general way by perpendicular lines the time-range of the kinds just mentioned, and remarks in following paragraphs further explain the known range of some of the subordinate, as well as that of the principal kinds.

The horizontal spaces of the table represent the systems or stages of the geological scale. The proportionate width of the spaces which contain the names of those systems or stages is not intended to indicate the actual ratio of geological time for each, but it may be stated as the general opinion of competent investigators that the portion of the scale from the Cambrian to the Carboniferous inclusive represents a much greater length of time than does the portion from the Trias to the Tertiary inclusive. In other words, it is generally believed that the Palæozoic portion of the geological scale was of much longer duration than was that of the Mesozoic and Cenozoic portions together.

The perpendicular lines in the table, which are placed singly or in pairs or groups under letters of the alphabet from A to G

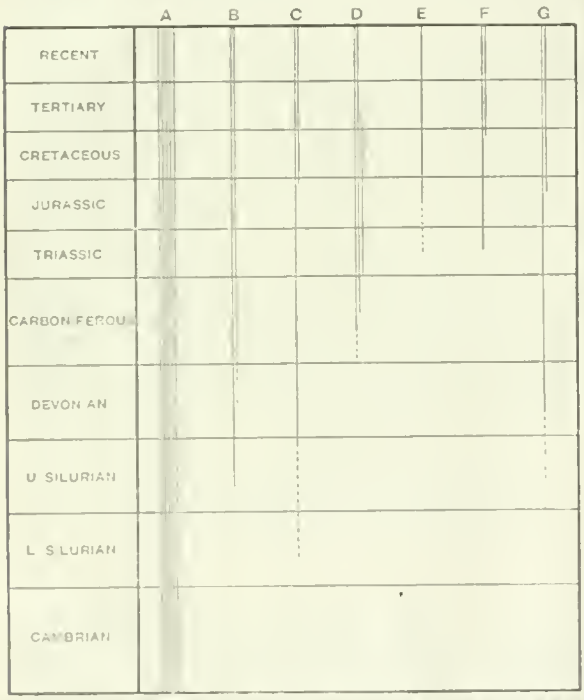


TABLE showing [illegible] (A) Marine invertebrates, (B) non-marine and land invertebrates, (C) fishes, (D) batrachians and reptiles, (E) birds, (F) mammals, and (G) land plants.

indicate, approximately, the time-range of the kinds of animals and plants which have already been mentioned, and which for convenience of reference are again recorded with their corresponding letters at the foot of the table. This method of grouping the different kinds of animals and plants, as already referred to, is adopted only for present convenience in making comparisons of chronological values. All the principal kinds of animals recognised in the usual systematic classification are, however, included in these special groups, the few that are omitted being regarded as of little or no importance in this connection. The dotted portion of certain of the lines indicates approximately the real extent of the time-range which is shown by them, because of imperfect or doubtful representation of those kinds by discovered fossil remains.

Of all the animals which have existed upon the earth, and of which remains have been discovered, only those of marine invertebrates have been found to range through the whole geological scale. The occurrence of these important portions of the animal kingdom is represented by the group of five perpendicular lines under the letter A. The marine invertebrate life thus represented includes the Protozoa, Cœlenterata, Annuloida, Annulosa, and Mollusca, the latter including the Molluscoida. That is, it includes five of the six sub-kingdoms or branches of the animal kingdom.

The non-marine and land invertebrates, the time-range of which is intended to be represented in the table by the two perpendicular lines under the letter B, are only insects and fresh-water, brackish-water, and land molluscs. The discovered fossil remains of all other non-marine and land invertebrates are regarded as either too rare or too unimportant to be profitably considered in the comparisons which are to follow. The longer of the two lines may be taken as representing the known time-range of insects, and the shorter that of land and non-marine mollusca.

The pair of perpendicular lines in the table under the letter C shows the approximate time-range of all the various kinds of animal remains which have been referred to the fishes. The shorter of the two lines indicates the known range of the teleostean fishes, and the longer that of the other kinds, the latter including certain forms that differ materially from any living fishes.

The time-range of batrachians and reptiles, so far as it is known, is shown by the three perpendicular lines in the table under the letter D, that of the dinosaurs alone being represented by the shortest line of the three.

The known time-range of birds is represented by the single line under the letter E. It is here assumed that most, if not all, the fossil tracks found in Triassic strata, and formerly referred to birds, are those of dinosaurs.

The two lines in the table under the letter F represent the known time-range of mammals, the longer line representing that of the non-placental, and the shorter that of the placental mammals.

The known time-range of land plants is represented by the two lines under the letter G. The shorter line represents the range of the dicotyledons and palms, and the longer one that of all other kinds. The algæ and diatoms are omitted from the table, as being of little or no importance in the comparisons and discussions which are to follow.

The earlier portion of the time-range for each of the kinds of animals and plants, as shown by the perpendicular lines in the table, is naturally more incompletely and indefinitely represented by fossil remains than is the later portion, because of the smaller variety and greater rarity of those earlier remains, and also in most cases because of the increasing difference in character from living forms which is observable from later to earlier formations. In some cases, however, the early portion of the time-range as it is now known begins so suddenly, and with forms of such high biological rank, as to make it evident that its real beginning was much earlier than it has yet been proved to be by actual discovery of fossil remains. The last-mentioned fact is of great importance in many respects, but it does not necessarily affect the question under consideration, because all estimates of the relative chronological value of fossil remains must be confined to the kinds already known, and the application of such estimates must refer only to those portions of the geological scale in the strata pertaining to which the remains are known to occur.

It has been shown that it is the general advancement in biological rank for all organic forms and for the whole of geological time that constitutes the ideal ultimate standard of measure for that time. It does not necessarily follow, however, that the geological scale is actually based upon the combined average rate of advancement of all those forms, because this is a factor which cannot be definitely ascertained. Still, in all cases it is necessary to apply that idea so far as is practicable.

In view of the facts recorded in the preceding paragraphs, the highest estimate of chronological value must necessarily be placed upon the fossil remains of those kinds which have existed under the most nearly uniform conditions through the whole of geological time, and which give evidence of the most nearly uniform advancement in biological rank. Accordingly, the remains of marine invertebrates possess legitimate claims to a higher estimate of chronological value than do those of any other kinds of animals or of plants.

It is true that the rate of development in biological rank of marine invertebrates does not embrace the entire advance for the whole animal kingdom, because it begins in the scale as it is now known with many highly organised forms, and ends without including the vertebrates; but this fact does not affect any of the

necessary elements of their superior chronological value, which have just been mentioned. The following summary of facts relating to the marine invertebrates show their principal claims to the highest estimate of value in characterising the divisions of the geological scale, and in determining the geological age of the strata in which their remains are found.

The marine invertebrates embrace five of the six sub-kingdoms or branches of the animal kingdom.

They have coexisted in every stage of geological time, while the known time-range of other animals, as well as of land plants, has been very much less.

The preservation of their remains having been a natural consequence of the character of their habitat, they are faunally more complete than are those of any land animals, and for the same reason they are florally more complete than are remains of land plants.

They all lived under the same or closely similar conditions, and those conditions were more nearly uniform throughout all geological time than were those under which any other forms of life existed. Their remains have, therefore, produced a more nearly uniform chronological record.

Their relations to one another were wholly congruous, while the relations of all of them to all non marine faunas and land floras was more or less incongruous, and in many cases extremely so.

The formations containing their remains are for the whole world and the whole of the geological scale far in excess of those which contain the remains of any other forms of life, especially the remains of land plants and land animals.

CORRELATIVE GEOLOGY AND ITS CRITERIA.

The term "correlative geology" is not in common use, but it is adopted as a present convenience in discussing the correlation of assemblages of strata as divisions or subdivisions of the geological scale as it is developed in separate regions, and the identification of formations within one and the same district or region. As here used, the term correlation refers to geological systems or other comprehensive series of stratified rocks which occur in different and more or less widely separated parts of the world, between which parts there is no physical continuity of strata, or none that it is possible to discover. Correlation applies to general geology, identification to local or regional investigations.

The latter may be discussed under two heads, direct and relative. Direct identification applies to formations the characteristics of which at one or more localities have been ascertained, and as these are naturally of limited geographical extent, the application is similarly restricted.

Although fossils in all cases constitute not only much the most, but usually the only, trustworthy criteria for such indentification of formations as is indispensable in the study of structural geology, the various kinds differ materially as to their relative value. This value, however, has no necessary relation to that which they may possess as indicators of geological time, or of the correlation of the strata containing them with those of other parts of the world. The two values are distinct, although one kind of fossil remains may often possess both.

While fossil remains unquestionably afford the most trustworthy and often the only means of either direct or indirect identification of formations, in the absence of these means the geologist often reaches conclusions in this respect by methods of reasoning that it would be difficult even for himself to formulate, and these conclusions are valuable in proportion to his acquirements and experience. Among these less clearly definable methods is that which takes cognisance of homogeny; that is, of a method in connection with which certain inherent lithological and stratigraphical characteristics, which are possessed by a formation or series of strata in one part of a given region under investigation, are accepted as evidence that it had a common origin with a formation or series presenting similar characteristics in another part of the same region. Such a conclusion necessarily implies that originally there was physical continuity of similar strata between such localities, and that it has either been destroyed or obscured.

This method of identifying formations is one of minor importance as compared with that which is based upon fossil remains, but unfortunately it has, especially within the last few years, been adopted by certain geologists in charge of important works, almost to the entire exclusion of palæontological considerations. Although it cannot be denied that in the hands of an experienced and broad-minded investigator this method of identifying formations is of great value, the fact remains that some of the most grievous mistakes that have ever thrown discredit upon geological investigation have occurred by its adoption to the exclusion of palæontological evidence.

It has been the custom of a large proportion of geologists to regard the geological scale as it has been established in Europe as the absolute standard for the whole earth. A necessary consequence of this view is their assumption that the systems which physically constitute that scale, and at least most of the divisions of those systems, may not only be recognised, but as clearly defined in all parts of the earth as they are in Europe, if in those parts contemporaneous deposits were made and still remain intact.

In view of known facts and principles, the idea held by the early geologists, as well as by some of those now living, that identity of fossil types proves synchronism or exact contemporaneity of origin of any two or more series of strata containing them, is quite untenable. The facts which have been presented also suggest that the term "homotaxy" must be used with some degree of latitude as to its application to the subdivisions of systems, because the order of sequence in the occurrence of the types which characterise them, respectively, in one part of the world is in another part sometimes partially reversed or partially interchanged. That is, the taxonomy of those divisions, as biologically indicated, is not the same for all parts of the world.

The presence in widely separated parts of the world of all the systems of the geological scale, as well as of some of their larger divisions, has been demonstrated by the labours of a multitude of geologists, so the fact of correlation is not called in question. The principal questions which are here raised concern the scope of correlation, or the limitation of the assemblages of strata, the relation of which to respective divisions of the scale is more or less obvious. These questions are of practical application in the study of the structural geology of any part of the world other than that in which the geological scale was established; but they are of such a character that they must be conventionally rather than arbitrarily determined.

For example, in discussing the questions which have arisen concerning the earlier and later limits of the systems of the geological scale in North America, the difference of opinion as to those limits have been wider and more various with regard to the later systems than to the earlier. This is because of the greater number and variety of the kinds of fossil remains to be considered in such discussions of the later systems. It is therefore evident that in reaching a conclusion as to the limitation of any of these systems, or of any of their subdivisions, it is necessary to take into consideration all available facts, physical as well as biological. It is equally evident that it is the duty of every American geologist to hold in abeyance any final decision as to the correlation of the groups of strata which he may study with the divisions of the European scale until all such facts have been duly and justly considered. In short, the idea of absoluteness in such cases is as much out of place as is the assertion or recognition of personal authority.

Although these remarks refer directly to North American geology and geologists, they are equally applicable to other parts of the world when reference is made to the scale as represented by the European rocks.

Notwithstanding the great excellence of the scale now in general use, and the fact that so little change has been made in it since it was first devised by the early geologists, the future progress of geological science will demand modifications the necessity for which will be especially urgent when the true character of correlation for all the principal parts of the earth has been ascertained. Hitherto correlation has been investigated with the single purpose of adjusting the series of formations which occur in each of the various parts of the world to the scale now in use; but although its general applicability to that purpose is not to be questioned, the ultimate result of the study of correlation will be to modify this scale and adjust it to the systematic geology of the whole earth. That is, the scheme of stratigraphic classification, which has been the main factor in adjusting the elements of systematic geology, must in turn be itself adjusted to the great system which it will have been the principal agent in producing.

CRITERIA OF PAST AQUEOUS CONDITIONS.

Among the more conspicuous facts in geology are some of those which relate to the manner of origin as well as to the original and present condition of the sedimentary formations. These subjects have already been discussed, and among those discussions are

some references to the character of the water in which each formation was deposited. Studies of the sedimentary formations, especially those made from a biological standpoint, have demonstrated that the bodies of water in which they were deposited were of the various kinds that are now known: that is, some were marine, some fresh, and some brackish.

Upon physical evidence alone, it is not practicable to satisfactorily classify the sedimentary formations of the earth in such a manner as to serve the purpose of thorough geological investigation. Therefore such data are in this, as in most other cases, chiefly valuable as being accessory to the evidence afforded by biological data.

The biological criteria which are relied upon by geologists to distinguish from one another the sedimentary formations which have been produced in marine waters, or in those of inland seas, lakes, rivers, or estuaries, relate to the characteristics of faunas which now inhabit those waters respectively, and to the differences from one another of such faunas. That is, the conclusions which geologists reach concerning the questions just indicated are based upon now-existing physical conditions, upon the known character, structure, and habits of animals with relation to those conditions, and upon the assumption that in past geological epochs animals of a given character and structure had similar habits, and lived under conditions similar to those which are congenial to their living congeners.

The various bodies of water which existed during geological time, and which constituted the habitat of aquatic animals, were of the same kinds that now exist, namely, marine and fresh, together with those of the various intervening grades of saltness. Although it is probable that the marine waters of early geological time were not so salt as those of the present oceans, it is believed that this difference in saltness has not been so great as to make any appreciable difference as to legitimate conclusions of the kind that have been indicated. It seems to be especially evident that this difference has been thus inappreciable since the close of palæozoic time, since which time the greater part of the known unmistakably non-marine formations were deposited.

If all the known now living members of a given family are confined to marine, or to fresh waters, as the case may be, it is assumed that the habitat of the extinct members of such families were similarly restricted, and that the presence of fossil remains of such animals in a given formation, is, in the absence of conflicting facts, sufficient evidence of its marine origin on the one hand, or of its fresh-water origin on the other. Again, if a given family is known to have representatives now living in marine, brackish, and fresh waters, respectively, it is assumed that it had a similar range of habitat during past geological epochs. Therefore, the discovery in a given formation of fossil remains of a single representative of a family having such a varied range of habitat is not of itself sufficient to enable one to decide whether it was of marine, brackish, or fresh-water origin, and other evidence must be sought.

The criteria of past aqueous conditions here discussed are, of course, only such as may be derived from sedimentary formations and their contents. It cannot be said that there are any fully trustworthy physical criteria because a non-marine formation rarely presents any condition of stratification, or any lithological character, which is not observable in some marine formations. Still, there are many more or less valuable indications which may be observed and to some degree relied upon in the absence of fossil remains.

For example, although considerable accumulations of calcareous strata are sometimes found among the generally arenaceous strata of fresh-water formations, they have never been found to contain any important accumulations of regularly bedded limestones. Furthermore, estuarine deposits are often still more of a detrital character than are fresh-water formations, and also they more rarely contain calcareous layers. Therefore, if one should encounter a series of regularly bedded limestones, either magnesian or fully calcareous, he will rarely, if ever, be at fault in regarding them as of marine origin even without biological evidence.

In a large proportion of the non-marine formations, the stratification is less regular than is usually the case with marine formations. Still, this is by no means a certain criterion, and in some cases non-marine formations are found to rest so conformably upon the marine and to be so conformably overlain by them as to give little indication of the great difference in the condition of their origin.

These examples serve to show how indefinite is the character of physical evidence as to the past aqueous conditions under which the various sedimentary formations have been produced, but they serve to emphasise a statement of the fact that almost entire reliance must be placed upon the evidence furnished by fossil remains.

With reference to general indications of difference between marine and non-marine formations which are furnished by their fossil remains, we observe that a conspicuous difference lies in the comparative abundance and variety of forms of life which the fossil faunas of the formations respectively represent. Marine waters have always teemed with life in a wonderful variety of forms, and their fossil remains are proportionally abundant. The variety is less in brackish waters, and least of all in lacustrine waters. It is true that ichthyic life is abundant in some fresh waters, but never so generally abundant or so various as in marine waters. It is also true that molluscan life is often locally abundant in shallow fresh waters, but, as already several times mentioned, the variety is extremely meagre. All these peculiarities are distinctly observable among the fossil faunas of the non-marine formations.

Other general indications of difference between marine and non-marine formations are furnished by remains of land plants and animals. Open-sea formations are naturally free from any vegetable remains derived from the land, although coal and other materials of vegetal origin are not unfrequently found alternating with layers containing marine fossil remains. These, however, are regarded as cases of emergence of the bottom of shallow sea waters and the subsequent subsidence of the same as plant-laden marshy land. It is a matter of fact, the reason for which has been suggested in preceding sections, that plant remains of any kind, especially such as are in a classifiable condition, have so rarely been found associated with remains of denizens of marine waters, that the discovery of fossil plants in any formation is of itself presumptive evidence of its non-marine origin.

It has already been shown that the remains of land animals have so seldom reached marine waters, or, having reached them, they were probably so generally destroyed by the triturating action of coast waves, that the discovery of any of this kind of fossil remains in any formation may also be regarded as presumptive evidence of its non-marine origin.

The foregoing statements have been made with reference to indications which are either of a general character or without direct relation to the quality of the waters in which sedimentary formations have been deposited. All the direct evidence, as has been already fully stated, is derivable from the fossil remains of the denizens, especially the gill-bearing kinds, of the waters in which were deposited the formations under investigation.

Referring to the previous review of the animal kingdom, it will be seen that a large number of families of both fishes and invertebrates are confined to a marine habitat, and that every member of even some of the higher divisions is similarly restricted. For example, every known member of the classes Cephalopoda and Brachiopoda is confined to a marine habitat. It will also be seen that a certain small number of families, especially of the mollusca, are equally restricted to fresh waters. The significance of such cases as these has already been pointed out, but it is desirable to refer to them again.

Fossil remains representing any one of these kind of animals may be taken as positive evidence of the quality of the water in which the formation containing them was deposited, provided there shall be no room for reasonable doubt that the animals were really denizens of that water. That is, caution is necessary even in these more positive cases, especially when the amount of discovered fossil material is meagre.

Not only caution but the exercise of careful judgment is necessary in other cases. For example, it will also be seen by referring to the foregoing review that certain families, while most of its members are confined to one kind of water, may have one or more representatives in other kinds; and again, that certain families may have representatives in all the known kinds of habitable waters. In such cases as these it is plain that all evidence afforded by fossil remains, to be of any value, must be corroborated by other evidence.

Still, the cases are very few in which serious doubt need be entertained as to the true character of the water in which a given formation was deposited. This is especially true if the fossil remains are sufficient in quantity and perfection to approximately represent the whole fauna that lived in those waters. Indeed, if the facts which are recorded in this review are borne in

mind, there need be no more doubt as to what was the quality of the water in which any given formation was deposited, than might arise concerning any other geological observation.

THE CLAIMS OF GEOLOGICAL SCIENCE UPON INVESTIGATORS, MUSEUMS, &C.

With reference to the ordinary pursuits of life it can hardly be said that, apart from a natural demand for respectable emulation, one's occupation has any claims upon him other than those which are either conventionally or legally imposed by society upon every one of its members. The geological investigator, however, is not only amenable to all such claims, but to others of a different nature which, although not enforceable by legal, and unfortunately not yet by conventional, penalties, are not less imperative in their character.

Much might be said in favour of the demands which may be made in the name of science upon the individual on the ground of justice and of moral and social ethics; but all considerations of this kind will be omitted, reference only being made to those claims which are supported by the urgent necessities of science itself. Claims of the kind referred to might be made in favour of all the various divisions of science; but on the present occasion the discussions will be confined to those which pertain to biological geology, including both its structural and systematic branches. With reference to the manner in which the subject is presented, it is proper to say that thehomiletic form has not been adopted merely from personal preference, but because it appears to be in the present case a proper and effective, if an indirect, method of calling attention to prevalent errors, and of suggesting necessary improvements in certain prevalent methods.

These claims of science will be considered not only with reference to the individual investigator, but to associations, museums, and geological organisations. Those which may be made upon the individual investigator relate to the manner of prosecuting his work and of publishing its results, and also to his final disposition of the evidence upon which his conclusions are based. Claims upon associations or societies relate to the character and methods of publication; those upon museums, to the conservation and installation of fossil remains, and of the records pertaining to them; and those upon organisations, to the preservation of the integrity of geological science.

In considering the claims of science upon the individual, it is desirable to make some reference to the amateur as well as to the special investigator. This recognition of non-professional work is desirable because the general subject of geology has acquired such a hold upon the popular mind, and the opportunities for making observations with relation to it are everywhere so common, that in every civilised country there is a multitude of persons who are in the habit of making more or less critical observations. Notwithstanding the usual limited and desultory character of such observations, they have often contributed materially to the general fund of geological knowledge, especially when accompanied by a faithful record and preservation of evidence. Indeed, some of the most valuable facts in geology have been brought out by amateur observers, who themselves were hardly conscious that they had made their way alone to the frontier of acquired knowledge; and from the ranks of such observers have arisen many of the leaders in geological investigation.

It has been shown that systematic geology could have no existence without the use of fossil remains, and also that without their use structural geology would be reduced to mere local and disconnected studies. It has also been shown that to arrive at a just estimate of the value of fossil remains in these branches of geology they must be thoroughly and systematically studied as representatives of faunas and floras, as well as tokens of the formations in which they are found. The proper collection and preservation of fossil remains is therefore a subject of the greatest importance. In view of these facts it is the plain duty of every geologist, upon beginning a piece of field-work in structural geology, to accompany every step of his examination of the strata by as full a collection as possible of the contained fossils, and to preserve them, together with notes recording the results of his observations and a statement of all the facts relevant thereto.

Fossils thus collected, and the facts concerning them recorded, become invested with a value which differs materially from that which is possessed by ordinary property, and the claims of science upon them and upon the investigator with relation to them at once begin. These claims, as just intimated, require that a careful descriptive record be made of the stratigraphical conditions under which the fossils are found, including a directive record of the locality and designation of the stratum from which they were obtained. They also require that these records should be inviolably preserved and made inseparable from every specimen by indices that shall be as intelligible to other investigators as to the original observer.

Apart from the claims of science such precaution is necessary, because reliance upon memory alone is always unsafe in the most favourable cases, and it can at best give rise only to such oral traditions as are out of place in scientific work. The immediate preparation of the records and indices just mentioned is also necessary, because, while every specimen is at all times competent to impart to an investigator all obtainable knowledge of its own character, it can of itself convey no information as to its original locality and stratigraphic position. With this information secured for a collection of fossils they may be made at all times available as aids to scientific research, not only by the collector, but by all other investigators.

The claims of science also require that immediately upon the completion of the original study of fossils thus collected and recorded, they shall be placed where they will be freely accessible to the scientific public, and that reference to their place of deposit shall be made in connection with their publication. It is needless to say that the only suitable places for such deposit are public museums. It is only when this indispensable evidence is thus made accessible that the public can exercise that arbitration over the accumulated results of the labours of investigators which has been shown to be imperative.

The preparation and publication of complete records concerning the locality and strata from which fossil remains are obtained are necessary even from a biological point of view alone, especially when those remains are studied with reference to the range of organic forms in time, and without such records fossil remains are comparatively worthless as aids in geological investigation. It is unfortunately true that a not unimportant proportion of the palæontological material contained in our best museums is without these essential records, and that many of the publications containing descriptions and illustrations of fossil remains give no satisfactory information as to the localities and strata from which they were obtained, or of the final disposition of the specimens. In such cases those authors and collectors have evidently assumed to decide for themselves and for science the exact taxonomic position in the geological scale of the strata from which their fossils came. In omitting such records as have been referred to, they seem to have considered any information unnecessary that would enable the scientific public to repeat their observations upon their specimens, or those which they may have made in the field, or to learn the biological characteristics of the formations from which their collections were obtained other than those which may be suggested by their own partial collections and their necessarily imperfect descriptions. It is doubtless true that such omissions have been largely due to an honest lack of appreciation on the part of authors and collectors of the importance of preserving such records, but it is to be feared that in some important cases the omissions or suppressions have been intentional. In the former class of cases the fact can only be deplored, but in the latter every geologist is justified in feeling that a crime has been committed against science.

The claims of geological science upon associations and societies are so generally and justly recognised, that only the one which relates to the manner of publishing the results of investigation need be referred to in this connection, and this reference will be confined to the necessity of enforcing the claims upon individual investigators which have already been discussed. This claim may be sufficiently indicated by reference to those last mentioned, and by the remark that if it is the duty of individuals to publish records of their observations in the manner that has been stated, it is plainly the duty of those persons who may be in charge of the means of publication to refuse to publish the writings of those authors who do not conform to that requirement.

The facts and principles which have been stated fully warrant the statements that individual authority can have no existence with relation to geological science, that the public must be the final arbiter of all questions concerning the value of proposed contributions to its advancement, and that a public exposition should be made of the evidence upon which any contribution to biological geology is based. In accordance with the last-named requirement it is necessary to consider the claims of this branch

of science upon museums, the force of which is apparent when it is remembered that the material pertaining to it therein stored constitutes the vital evidence of the value of all contributions to its advancement, and that without such evidence this branch of science would be reduced to a mass of personal testimony.

In view of the great scientific value of fossil remains the following remarks are offered concerning the precautions which are necessary in their preservation. It is true that most, if not all, these precautions are observed in a large part of the principal scientific museums of the world, but it is also true that much remissness in this respect has occurred in others. Besides the propriety of referring to the latter fact, these remarks are necessary to complete my statement of the claims of science which constitute the subject of this essay.

Three general classes of specimens of fossil remains should be recognised in museum collections, namely, typical, authenticated, and unauthenticated. Under the head of typical or type specimens are included not only those which have been described and figured in any publication, whether original or otherwise, but those which have in any public manner been so used or referred to. While all such specimens as these should at all times be accessible to any competent investigator, the risk of loss or injury is so great that they should in no case be allowed to be taken from the museum building in which they are installed. Such specimens are in a peculiar sense unique, and there can be no substitution and no equivalent in value. Their loss greatly reduces the value of every publication any part of which is based upon them, and to that extent retards the advancement of science. It is not enough that other, and even better, specimens of presumably the same species may be discovered; the former constitute the original, the latter only suppositious evidence. Besides the risk of loss or injury to type specimens by removal from the place of their instalment, their absence is a disadvantage to science. That is, no one investigator should be allowed their use to the exclusion of any other.

The term "authenticated specimens" is here applied to such as have been studied and annotated by competent investigators and properly installed. Such material constitutes the bulk of every important museum collection, and next to the type specimens already mentioned, they are most valuable. Their increased value is due to the scientific labour that has been bestowed upon them, and it needs only the additional labour of publication to constitute them type specimens and to make them of like value. Authenticated specimens when installed are ready aids to all investigators of such value, that even the temporary removal of any of them from a public museum is, to say the least, of doubtful expediency.

Unauthenticated specimens are, of course, those which have not been studied and installed, and they constitute the great mass of material from which authenticated and type specimens are drawn. Among them are those which constitute the material evidence upon which original observations in biological geology are based. If these are accompanied by the records and descriptive notes which are essential to their value, they constitute proper material for acceptance by museum authorities; but if not, their instalment should be refused, whatever their character may be. That is, to apply a statement made in another connection, no specimen of fossil remains should be admitted to permanent installation in any public museum which is not accompanied by such a record of the locality and stratum from which it was obtained, as will enable any investigator to revisit the same. In every case of instalment such records should be so connected with every specimen as to be readily accessible, and so arranged that the danger of loss or disconnection shall be reduced to a minimum.

The foregoing discussion of the claims of science upon museums is intended to embrace reference only to those which are devoted to the preservation of material pertaining to biological geology, but they are of more or less general applicability. These partial [illegible] demonstrate the important relation that museums hold to science and to civilisation as centres of learning and [illegible] of the evidence concerning acquired knowledge. Museums should not only be made safe treasure houses of science, but they should be what their name implies—temples of study, [illegible] open to all investigators.

The claims of science upon geological organisations cannot be [illegible] here, but because the ratio of power for the advancement or retardation of science possessed by such organisations is much greater than that of individuals working [illegible], it is desirable to make this brief reference to them. That power increases also with the ratio of the extent of the organisation, and it is largely centred in the director. His responsibility, especially if his organisation is a large one, is peculiar, and, to himself, of an unfortunate character. That is, while all, or nearly all, the advancement of science that may be accomplished by the organisation is the work of his subordinates, retardation, if it should occur, is mainly due to his failure to require that each branch of investigation should be prosecuted in accord with all others, and the case would be little less than disastrous should he himself favour *ex parte* methods, or fail to require a symmetrical development of the work in his charge. The claims of science upon geological organisations are therefore really claims upon their directors, and they are more responsible than any other class of persons for the preservation of the integrity of geological science.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

AT a meeting of the Council of University College, Dundee, last week, it was announced that the trustees of the late Miss Margaret Harris had allocated a number of securities, valued at nearly £14,000, to establish a chair of Physics in the College, as recommended by the University Commissioners. The Council resolved to institute immediately a chair of Natural Philosophy; and an appointment will be made before the beginning of next session. Hitherto the classes of Mathematics and Physics have been combined. The salary will be £400 with share of the fees.

THE invaluable *Record* of technical and secondary education continues, in the quarterly number just issued, the review of the work done by the Technical Education Committees of the English County Councils, commenced in the preceding issue. A summary is also given of the work of the Scotch County Councils, from which it appears that, out of a total of thirty-three County Councils, twenty-four are devoting the whole, and seven a part, of their grants to educational purposes, while two counties are applying the whole of the fund to the relief of the rates. Out of a total sum of £25,157 distributed among the County Councils of Scotland, £22,491 was devoted to education in the year 1893-94. Mr. P. J. Hartog contributes to the *Record* an illustrated description of the Owens College, Manchester.

THE Town Trustees of Sheffield have (says the *Athenæum*) voted a sum of £10,000 towards the endowment of Firth College, with a view to enabling the authorities to affiliate it to Victoria University. The actual endowment of the College is £23,000, in addition to its income of £1200 from the State and £800 from the Corporation. It is understood that a total of £50,000 would be sufficient, but no more than sufficient, for the purpose of affiliation. A further sum of £5000 has been conditionally promised by Sir Henry Stephenson, and a public appeal is contemplated for the remaining £12,000.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for March 1895 contains:—On the variation of the tentaculocysts of *Aurelia aurita*, by Edward T. Browne. (Plate 25.) Of 359 Ephyræ collected in 1893, 22·6 per cent. were abnormal in possessing more or less than eight tentaculocysts; and of 1156 collected in 1894, nearly the same percentage, 20·9 was obtained. Of 383 adult Aurelia collected in 1894, 22·8 per cent. were abnormal.—On the structure of *Vermiculus pilosus*, by E. S. Goodrich, gives a detailed account of this interesting Oligochæte, found near Weymouth in 1892. (Plates 26-28.)—On the mouth parts of the Cypris stage of Balanus, by Theo. T. Groom. (Plate 29.) "It may be regarded as tolerably certain that: (1) The antennæ of the Nauplius become definitely lost with the moult resulting in the production of the Cypris stage. (2) The biramous mandibles of the Nauplius become reduced at the same time to the small mandibles, the ramus being probably preserved in the form of the small palp. (3) The first pair of maxillæ arise behind the mandibles, and at a later date, as a small pair of foliaceous appendages. (4) The second pair of maxillæ arise still later, just in front of the first pair of thoracic legs (cirri)."—A study of Coccidia met with in mice, by J. Jackson Clarke. (Plate 30.)—Observations on various Sporozoa, by the same. (Plates 31-33.)—Revision of the genera and species of the

Branchiostomidæ, by J. W. Kirkaldy (Plates 34 and 35), enumerates two genera, Branchiostoma (as sub-genera, Amphioxus, Heteropleuron) and Asymmetron. A new species of Heteropleuron, *H. cingalense*, is described.—On Sedgwick's theory of the embryonic phase of ontogeny as an aid to phylogenitic theory, by E. W. MacBride.

June.—On the anatomy of *Alcyonium digitatum*, by Prof. Sydney J. Hickson (Plates 36-39), gives a brief account of our knowledge of the anatomy of Alcyonium, the general morphology, the English species, their geographical and bathymetrical distribution, then the general anatomy, followed by the minute anatomy of the ectoderm, nematocysts, stomodæum, mesenterial filaments, mesoglœa, spicules, endoderm, ovaries and testes, the buds, concluding with a note on the circulation of the fluids in the colony and on the digestion. In the history of investigations, Pallas' name is not alluded to, and yet he deserves to be quoted as having even before Savgny assigned correct characters to Alcyonium ("Hist. nat. des Coralliaires," Milne-Edwards, tome 1, p. 114), and the "Contribution a l'anatomie des Alcyonaires," by Pouchet and Myevre, dates, if we mistake not, before Vogt and Jung's account in their "Lehrbuch," and while it may be of little use to the student, it is not without interest, as it figures, after a fashion, the nematocysts in *A. digitatum*, and this possibly for the first time (1870). Prof. Hickson, however, leaves all previous writers far behind in his modern treatment of this subject, and if he keeps his promise of publishing an account of the maturation and fertilisation of the ovum and its development, he will leave us under still further obligations, for except Kowalevsky and Marion's important papers on the developmental history of *Clavularia crassa* and *Sympodium coralloides*, we have but little light on Alcyonarian development.—Note on the chemical constitution of the mesoglœa of *Alcyonium digitatum*, by W. Langdon Brown. It is chiefly composed of a "hyalogen" prior to the conversion of the hyalogen into hyalin the mesoglœa will yield a mucin; it also contains a small amount of an insoluble albuminoid body, whose nature was not determined; it does not contain gelatine or nucleo-albumen. A study of metamerism, by T. H. Morgan. (Plates 40-43). The author in a long memoir, that does not admit of being briefly abstracted, thinks that the cases he cites show very positively that the variations appearing in a radiate animal must have come simultaneously and all together into the antimeres; he thinks few will doubt that the relation existing between repeated organs in a radiate animal is at bottom the same relation existing between the right and left sides of the body of a bilateral animal. Mivart and Brooks have emphasised the further fact that the relation between the right and left sides of the body is the same relation that exists between the serially repeated parts of a metameric animal; and he concludes that if this line of argument be admitted, it puts the problem of metamerism into a large category of well-established facts.—On the Cœlom, genital ducts, and Nephridia, by Edwin S. Goodrich. (Plates 44-45). The chief object of this paper is to call attention to the theory, "that the cavity which is known as the cœlom in the higher Cœlomata is represented by that of the genital follicles in the lower types of that grade."

American Journal of Science, July.—On the pitch lake of Trinidad, by S. F. Peckham. This pitch lake is situated near the village of La Brea, on the Gulf of Paria. At first sight it appears to be an expanse of still water, frequently interrupted by clumps of trees and shrubs, but on a nearer approach it is found to consist of mineral pitch with frequent crevices filled with water. The consistence of the surface is such as to bear any weight, and it is not slippery nor adhesive. It is about 100 acres in extent. It occupies a bowl-like depression in a truncated cone on the side of a hill covered with tropical jungles. The cone consists of both asphalt and earth. A heavy stream of asphalt has overflowed to the sea, forming a barrier reef for a considerable distance. Asphalt has also overflowed to the south, and the general appearance of the escarpment seems to indicate that at some remote period the basin now occupied by the lake had been filled some three feet higher than the present level. It occupies what appears to be the crater of an old volcano. Some diggings have been pushed to forty feet without reaching the bottom. There is a steady outflow towards the sea through the side of the cone. The Trinidad Bituminous Asphalt Company have lately run a tramway from the pier through the lake and back, so as to facilitate the removal of the material. This tramway in crossing the lake is supported on palm-leaves, some of which are 25 feet long, and this plan has answered every purpose.—On some reptilian remains from the Triassic of Northern California, by John C. Merriam. The author gives a description of some of the few Californian Mesozoic reptiles. One of these resembles *Ichthyosaurus*, while the other is described as *Shastasaurus Pacificus*.—A further contribution to our knowledge of the Laurentian, by Frank D. Adams. This paper is accompanied by a map of a portion of the edge of the Archean protaxis north of the island of Montreal, Quebec. There are in the district considered at least two distinct sets of foliated rocks. One of these represents highly altered and extremely ancient sediments, while the other is of igneous origin.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 16.—"On Measurements of Small Strains in the Testing of Materials and Structures." By Prof. J. A. Ewing, F.R.S.

The paper describes a new form of "extensometer," or apparatus for measuring the elastic stretching of bars subjected to pull in the testing machine or otherwise. At the two extremities of the length under test, which is usually eight or ten inches, two cross-pieces are attached to the rod by means of a pair of diametrically opposed set-screws. Each piece is separately free to oscillate about the line joining its screw points, since it touches the rod under test at no other place, but the two pieces are caused to engage with each other in such a way that when the rod extends the end of one of the pieces becomes displaced through a distance which is proportional to the extension. The amount of this displacement is measured by means of a microscope attached to the other piece. The whole apparatus is self-contained, and the parts are arranged to have no unnecessary constraint. Its indications show the mean extension taken over the whole section of the rod, and are independent of any small amount of bending or twisting which the rod may undergo as it is stretched. The microscope is furnished with an eye-piece micrometer which reads the extension to $\frac{1}{50000}$ inch, and a calibrating screw is provided for testing and setting the micrometer scale. Two forms of the instrument are described, one suitable for laboratory use when the specimen under test stands vertically, and the other applicable to rods in any position, such as the members of bridge or roof frames *in situ*. In the laboratory use of the instrument the elastic properties of the material are examined by observing the strains under known loads; in the application to structures the object is to determine experimentally what the stress on any member is, from observation of the strain, the modulus of elasticity being assumed.

The author describes a number of observations made with the new extensometer, chiefly on rods of iron and steel. The following readings refer to successive loadings of a bar of steel, which conforms closely to Hooke's Law, the loads being well within the primitive elastic limit. They serve to illustrate the sensibility of the instrument. The zero of the extensometer was set at 400, and the unit of its scale was $\frac{1}{50000}$ inch. The bar was $1\frac{1}{4}$ inch in diameter, and the length under test was 8 inches.

Load in tons.	Extensometer readings.			Differences.		
	First loading.	Second loading.	Third loading.	First loading.	Second loading.	Third loading.

$17\frac{1}{2}$	830	829	830	61	61	62
20	892	891	891	62	62	61
0	400	400	400	492	491	491

In other experiments the rod under examination was allowed to become overstrained, that is to say the load was increased until the elastic limit was passed and permanent set was produced. In this condition the elastic properties of the rod are materially

different from its properties in the primitive state. On reloading the overstrained rod it is found that the proportionality of strain to stress no longer holds good, even under very light loads, and further that there is "creeping," or continued extension with the lapse of time, when any load is kept on for a few minutes. Again, on removing load the bar continues to retract for some time. These features of the overstrained state are most conspicuous in tests made directly after the overstrain has taken place. They tend to disappear if the bar is allowed to rest for some days or weeks. This elastic recovery with the lapse of time, some features of which have been already noted by Bauschinger and others, is less rapid in moderately hard steel than in iron or mild steel, apparently because the condition of overstrain requires a greater load to produce it. Thus a rod of common iron, overstrained so much that the yield-point was reached, was found to have made a practically complete recovery of its elasticity in five days. On the other hand, in a rod of rather hard steel, overstrained by applying a load of 11 tons and subsequently tested with loads of 8 tons only, the recovery was still imperfect after three weeks. The following table shows the progress of the recovery by giving the observed extensions of this rod after three intervals, namely ten minutes, one day, and three weeks, after the overstrain took place.

Load in tons.	Ten minutes after overstrain.		One day after overstrain.		Twenty-one days after overstrain.

The molecular settlement which is shown by these experiments to be going on for some time after overstrain has taken place, is known to be associated with a rise in the yield-point. Instances of this were given by the author in a previous paper (*Proc. Roy. Soc.*, No. 205, 1880).

May 30.—"On the Motions of and within Molecules; and on the Significance of the Ratio of the Two Specific Heats in Gases." By Dr. G. Johnstone Stoney, F.R.S.

In treating of molecular physics it is found to be convenient to widen the meaning of the word motion, so that it may be employed in regard to any change or event in which energy is stored, whether as kinetic energy, or as potential, electrical, chemical, or any other. It is in this generalised sense that the term is to be understood throughout this paper.

The aim of the paper is to demonstrate the existence of events going on within the molecules of matter which are so sluggish in affecting its pressure when in the gaseous state, or its temperature as measured by the thermometer, that it is only after millions of encounters that any manifestation of their having thus lost energy by conduction becomes appreciable; while these same events are prompt and active agents in other operations of nature through chemical reactions or by radiation.

Molecular events may be distinguished into A or external events, and B or internal. The external events are the movements of the centres of inertia of the molecules relatively to one another. They present themselves most conspicuously in those comparatively protracted journeys which the molecules of gases make between their much briefer encounters. By B motions are to be understood all events in which energy can be stored that go on within individual molecules, including rotation of the molecule if there be any movement of this kind, which, however, is not probable; along with every other relative motion of the parts of the molecule, movements within its ponderable matter, or of its electrons, changes in the configuration of its parts, and every other event within the molecule which can absorb and yield energy. The electrons are those remarkable charges of electricity, all of the same amount, which are associated in every chemical atom with each capacity that it possesses of entering into combination with other atoms.

It is convenient to distinguish the B or internal events, into Ba events between which and the A or translational motions of the molecules there is ready interchange of energy whenever encounters take place: Bc events which are so isolated that no such interchange takes place: and Bb events which lie between these extremes. In the struggle which takes place during an encounter, or in any one of the much longer intervals between two encounters, a Bb event will part with but very little of any excess of energy it may possess by conduction, *i.e.* by transferring energy over to A or Ba events. Nevertheless it may sustain an appreciable loss of energy in this way when the molecule has been buffeted in a sufficient number of encounters. This may easily occur in a time which seems short to us, since, if the gas be at atmospheric temperature and pressure, each molecule meets with some thousands of millions of encounters every second. Meanwhile, during this process, which is slow from the molecular standpoint, the Bb events, if they have electrons associated with them, may be engaged in a prompt and active exchange of energy with the æther by radiation.

In substances that are appreciably phosphorescent, it is easy to detect the presence of these Bb events; and, accordingly, a proof that they exist in this class of bodies is given in the paper. Moreover, by comparing the behaviour of different phosphorescent bodies, we learn that the degree of isolation in which Bb motions stand varies much from substance to substance. Motions of this type, which are so conspicuous in the bodies that can be perceived to be phosphorescent, are, of course, not confined to that class of bodies. In fact, they appear to be an important part of what is going on in every molecule of matter that can emit a spectrum, a description which probably embraces every molecule.

Since Bb motions are in various degrees isolated from the other events that are simultaneously going on in the molecules, it follows that in some gases the specific heat as determined by experiment will not be a definite quantity, but will partly depend on the duration of the experiment by which it is determined—*i.e.* upon whether or not there has been time for an interchange of energy between the Bb motions and the A and Ba events. This is likely in some gases to make an appreciable difference between determinations of γ—the ratio of the two specific heats—deduced from the observed velocity of sound in the gas (where the real experiment lasts only during one semi-vibration of the musical note employed), and determinations made by other experiments which require seconds, perhaps minutes, to carry them through.

There is reason to believe that it is with these Bb motions that the electrons within chemical atoms are chiefly associated, and that in most cases it is they which are concerned in luminous effects, whether in flames or when the gas is under the influence of electricity. Accordingly in both cases the luminous effects may have their origin in events that are in a considerable degree isolated from those that directly affect the thermometer; and wherever this is the case, the luminous effects will be in excess of what belongs to the temperature of the gas as determined by its power of communicating heat by conduction to bodies upon which its molecules impinge. This seems to have been proved by Prof. Lewes of flames (*Proceedings* of the Royal Society, vol. lvii. p. 404 and p. 467), and many phenomena indicate that it is also true of all gases which exhibit spectra of bright lines when in that state which has been miscalled incandescent.

It is specially to be noted that the interpretation usually put upon the value of γ in a gas has to be profoundly modified in consequence of the presence of Bb motions within the molecules, and of the degree in which the corresponding Bb motions of swarms of molecules are more or less linked together by the interaction that goes on between their associated electrons and the æther. (See Fitzgerald, in the *Proceedings* of the Royal Society, vol. lvii. p. 312.)

These examples may serve to show how a knowledge of the presence and activity of Bb motions supplies a clue to interpreting some of the phenomena of nature; and the extent of its applications may be judged by reflecting that it is electrons for the most part associated with Bb motions which appear to be primarily concerned in every chemical reaction and in all phenomena of radiation.

"On the Velocities of the Ions." By W. C. Dampier Whetham. A continuation of a former paper (*Phil. Trans.* 184, 1893 A, p. 337). The velocities of certain ions

during electrolysis are observed by tracing the formation of the precipitates which they give with a trace of a suitable indicator. Thus solid agar jelly solutions of barium chloride and of sodium chloride containing a little sodium sulphate were set up in contact, and a current passed across the junction. The barium ions form a little insoluble barium sulphate as they travel, and so their velocity can be measured. The specific ionic velocity under a potential gradient of one volt per centimetre can then be calculated, the area of cross section of the tube, in which the solutions are placed, the mean specific resistance of the solutions, and the strength of current being known. The following table gives a comparison between the results thus obtained and the numbers theoretically deduced by Kohlrausch from the migration constants and the conductivities of the corresponding aqueous solutions:—

	Calculated velocity in c.m. per sec.	Observed velocity in c.m. per sec.
Barium	0·00037	0·00039
Calcium	0·00029	0·00035
Silver	0·00046	0·00049
Sulphate group (SO_4)	0·00049	0·00045

June 20.—"On the Occlusion of Oxygen and Hydrogen by Platinum Black." Part I. By Dr. Ludwig Mond, F.R.S., Prof. W. Ramsay, F.R.S., and Dr. John Shields.

The authors describe some preliminary experiments on the occlusion of oxygen and hydrogen by platinum sponge and foil, which in general confirm the results obtained by Graham. At most only a few volumes of these gases are occluded by the more coherent forms of platinum.

After giving details of what they consider the best method of preparation of platinum black, they next describe some experiments which had for their object the determination of the total quantity of water retained by platinum black, dried at 100° C., and the amount of water which can be removed from platinum black at various temperatures in vacuo. As the result of these experiments they find that platinum black dried at 100° retains in general 0·5 per cent. of water, and this can only be removed in vacuo at a temperature (about 400°) at which the black no longer exists as such, but is converted at least partially into sponge. At any given temperature the water retained by platinum black seems to be constant. The density of platinum black dried at 100° C. is 19·4, or allowing for the water retained by it at this temperature, 21·5.

The amount of oxygen given off by platinum black at various temperatures was determined. Altogether it contains about 100 volumes of oxygen; the oxygen begins to come off in quantity at about 300° C. in vacuo, and the bulk of it can be extracted at 400° C., but a red heat is necessary for its complete removal. Small quantities of carbon dioxide were also extracted, chiefly between 100-200° C.

In determining the quantity of hydrogen occluded by platinum black the authors have carefully distinguished between the hydrogen which goes to form water with the oxygen always contained in platinum black, and that which is really absorbed by the platinum *per se*. Altogether about 310 volumes of hydrogen are absorbed per unit volume of platinum black, but of this 200 volumes are converted into water, or only 110 volumes are really occluded by the platinum. Part of it can be again removed at the ordinary temperature in vacuo; by far the larger portion can be extracted at about 250-300° C., but a red heat is necessary for its complete removal. The amount of hydrogen absorbed by platinum is very largely influenced by slight traces of impurity, probably grease or other matter which forms a skin over the platinum.

Platinum black in vacuo absorbs a certain quantity of hydrogen. On increasing the pressure of the hydrogen up to about 200-300 mm. a further quantity is absorbed, but after this pressure is almost without effect. By increasing the pressure from one atmosphere up to four and a half atmospheres, only one additional volume of hydrogen was absorbed. On placing platinum black charged with oxygen in an atmosphere of oxygen, and increasing the pressure to the same extent, eight and a half additional volumes were however absorbed.

Platinum black charged with hydrogen and placed in an atmosphere of hydrogen kept approximately at atmospheric pressure, and platinum black charged with oxygen and confined in an atmosphere of oxygen, behave quite differently when heated. In the former case hydrogen is immediately expelled on raising the temperature, whilst in the latter case oxygen is steadily absorbed until a temperature of about 360 C. (the temperature of maximum absorption) is reached, when on further heating oxygen begins to come off again.

Incidentally it was noticed that mercury begins to combine with oxygen at 237° C., and that a mixture of platinum black and phosphorus pentoxide absorbs oxygen at a high temperature, probably with the formation of a phosphate or pyrophosphate.

In the discussion of the results special reference is made to the work of Berliner and Berthelot, and it is pointed out that there is not sufficient evidence for the existence of such chemical compounds as $Pt_{30}H_3$ and $Pt_{30}H_2$. Moreover, the authors are of opinion that the heats of combination of hydrogen and platinum as determined by Berthelot and Favre are valueless, and that the heat which they measured is due for the most part if not entirely to the formation of water by the oxygen always contained in platinum black. It has yet to be *proved* that the absorption of hydrogen by pure platinum black is attended by the evolution of heat, and as regards the formation of supposed true chemical compounds, solid solutions, or alloys, the authors prefer to wait until sufficient data have been accumulated for an adequate inquiry before coming to any definite conclusion.

Royal Microscopical Society, May 15.—E. M. Nelson, Vice-President, in the chair.—Messrs. Watson and Sons exhibited a simple centring underfitting for use with any ordinary student's microscope.—The Chairman exhibited a new low-lower lens by Zeiss, and a new photographic lens.—Mr. W. C. Bosanquet read a paper on the anatomy of *Nyctotherus ovalis*.—Mr. G. C. Karop read a paper, by Dr. A. Bruce, describing a new microtome for cutting sections.—The Chairman announced that the library would be closed from August 12 to September 9, and that the next meeting would be on October 16.

Mineralogical Society, June 18.—Lewisite and Zirkelite, two new Brazilian minerals, by Dr. E. Hussak, of the Geological Survey of São Paulo, and Mr. G. T. Prior. Lewisite is a new titano-antimonate of calcium and iron, which was found with xenotime, monazite, cinnabar and other minerals in the heavy sand obtained by washing the gravel from a hill slope at the cinnabar mine of Tripuhy, Minas Geraes, Brazil. It is cubic, occurs in small brown translucent octahedra, and has the composition $5RO.3Sb_2O_5.2TiO_2$. Zirkelite is a new titano-zirconate of calcium and iron found in association with the new zirconia mineral baddeleyite in the magnetite-pyroxenite from Jacupiranga, São Paulo, Brazil. It is cubic, occurs in black octahedra, and contains about 80 per cent. of ZrO_2 and TiO_2. The authors describe the physical and chemical characters of the two minerals, and also give an account of the minerals associated with the Lewisite at Tripuhy; amongst these occurs sparingly a new titano-antimonate of iron, the description of which will be completed when more material is obtained.

PARIS.

Academy of Sciences, July 8.—M. Marey in the chair.—On the physical characteristics of the moon and the interpretation of certain surface details revealed by photographs, by MM. Lœwy and P. Puiseux. A general discussion of surface characters of the moon and their origin, and comparison with certain terrestrial features of possibly similar origin.—On the manner in which any confused but periodic wave-agitation becomes regular in the distance, reducing to a simple wave, by M. J. Boussinesq.

Action of zinc chloride on resorcinol, by M. E. Grimaux.—Comparison of the work done by muscles in the case of positive work with that developed in the corresponding case of negative work, by M. A. Chauveau.—Law of the distribution of mean magnetism at the surface of the globe, by General Alexis de Tillo.—Volumes of salts in their aqueous solutions, by M. Lecoq de Boisbaudran. The author considers all soluble substances to belong to a continuous series of which the members at the one end may show dilatation on solution, whereas the members at the other end may exhibit contraction under similar circumstances. He illustrates his theory by examples demonstrating that the former at low temperatures give contraction also on solution, whereas the bodies usually showing contraction on solution exhibit dilatation on solution in sufficiently concentrated

solutions.—On diphenylanthrone, by MM. A. Haller and A. Guyot. The researches detailed prove that the substance $C_{26}H_{18}O$ is diphenylanthrone, $C_6H_4 \begin{matrix} C(Ph)_2 \\ CO \end{matrix} \diagup C_6H_4$. From this established constitution, the phthalyl tetrachloride melting at 88° C. must have the dissymmetrical formula, $C_6H_4 \begin{matrix} \diagup CCl_3 \\ \diagdown COCl \end{matrix}$.—A new lymphatic gland in the European scorpion, by M. A. Kowalewsky. The gland described has already been made known by J. Muller, who, in 1828, termed it a salivary gland.—On the laws of friction in sliding, by M. Paul Painleve. The conclusion is deduced, from the singularities developed in the paper, that the empirical laws of friction are logically inadmissible (even for ordinary pressures and velocities) so soon as the friction becomes at all noticeable.—On the mirage effects and differences of density observed in Natterer's tubes, by M. P. Villard.—On explosive statical and dynamical potentials, by M. R. Swyngedauw.—On direct spectroscopical analysis of minerals and of some fused salts, by M. A. de Gramont. Determinations of the solubility, at very low temperatures, of some organic compounds in carbon disulphide, by M. Arctowski. Etard found the solubility of substances to be represented for other solvents than water by curves practically of hyperbolic form of which the branches respectively directed themselves towards the points of fusion of the solvent and of the dissolved substance; he even admitted that the solubility would be zero at the point of congelation of the solvent, and infinite at the point of fusion or ebullition of the dissolved substance. The author finds, with carbon disulphide, that the point of fusion of the solvent appears not to be an essential point on the curve of solubilities; and it is otherwise known that the property of dissolving is not an exclusive property of the liquid state of matter.—On some oxidising properties of ozonised oxygen and of oxygen in sunlight, by M. A. Besson.—Action of nitric oxide on some metallic chlorides: ferrous, bismuth, and aluminium chlorides, by M. V. Thomas. A fine red ferrous compound has been obtained of the formula $5Fe_2Cl_4.NO$. By decomposition of this, or by suitably heating anhydrous Fe_2Cl_4 in a current of nitric oxide, yellowish brown $Fe_2Cl_4.NO$ is obtained. A fine yellow bismuth compound and a pale yellow aluminium compound have also been obtained. They are very hygroscopic substances, and have the composition $BiCl_3.NO$ and $Al_2Cl_6.NO$ respectively.—Action of halogens on methyl alcohol, by M. A. Brochet.—On a physical theory of the perception of colours, by M. Georges Darzens.—On the presence and the *rôle* of starch in the embryonic sac of Cacti and Mesembryanthema, by M. E. d'Hubert. The observations favour the view that starch serves to preserve the embryonic sac in these plants in that state which characterises the ripe and readily fertilised sac.—On the tectonic characters of the north-west part of the Alpes-Maritimes department, by M. Leon Bertrand.—An inferior maxillary human bone found in a grotto in the Pyrenees, by MM. Louis Roule and Felix Regnault. From the characters of the bone described and other similar remains it is concluded that: In the time of the great Cave-bears, France was inhabited by a human race of normal height with a flat and powerful lower jaw.

NEW SOUTH WALES.

Linnean Society, May 29.—Mr. P. N. Trebeck in the chair. Oological notes (continued), by A. J. North. Note on the correct habitat of *Patella* (*Scutellastra*) *kermadecensis*, Pilsbry, by T. F. Cheeseman.—On two new genera and species of fishes from Australia, by J. Douglas Ogilby.—Descriptions of new species of Australian Coleoptera, Part II., by Arthur M. Lea. This paper comprises descriptions of over one hundred species, for the most part referable to the families *Malacodermidæ*, *Mordellidæ*, *Anthicidæ*, and *Corylophidæ*.—Life-histories of Australian Coleoptera, Part III., by W. W. Froggatt.—Description of a giant *Acacia* from the Brunswick River, New South Wales, by J. H. Maiden. This Acacia was collected by Mr. W. Bauerlen on Tergoggin Mountain and on Mullumbimby Creek, Brunswick River, N.S.W. As far as known, it is confined to brushes, as distinguished from open forest. It attains a height of 120 feet and a diameter of 5 feet; it is therefore one of the largest of the genus. Its closest affinity is with *A. binervata*, from which it differs in the structure of the flowers, seeds, and pod, and in other less important particulars. The inflorescence is in loose, elongated panicles or racemes, with peduncles in clusters. The flowers are few—never more than twenty—with villous petals and sepals, which are spathulate and tetramerous. The pod is nearly six lines broad, thin and straight. The author proposes the name of *Acacia Bakeri* for the species, in honour of his colleague, Mr. R. T. Baker.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Open-Air Studies: Prof. G. A. Cole (Griffin).—A Garden of Pleasure (E. Stock).—Dr. Schlich's Manual of Forestry, Vol. 4 (Bradbury).—The Alps from End to End: Sir W. M. Conway (Constable).—Nature *versus* Natural Selection: C. C. Coe (Sonnenschein).—Microbes and Disease Demons: C. Berdoe (Sonnenschein).—The Climates of the Geological Past: E. Dubois (Sonnenschein).—Physikalisch-Chemische Propaedentik Erste Halfte: Prof. H. Griesbach (Leipzig, Engelmann).—Die Physiologie der Geruchs: Dr. A. Zwaardemaker (Engelmann).—Experimental Plant Physiology: D. T. Macdougal (Holt and Co., New York).

PAMPHLETS.—Static and Dynamic Sociology: L. F. Ward (Boston, Ginn and Co.).—On Kaloxylon Hookeri and Lyginodendron Oldhamium: T. Hick.—On the Structure of the Leaves of Calamites (Manchester).—Report of the Trustees of the South African Museum for 1894 (Cape Town).—Returns of Agricultural Statistics of British India, &c., 1893-4 (Calcutta).—Studies on the Dissemination and Leaf Reflexion of Yucca Aloifolia: H. THURSDAY, JULY 25, 1895.

THE DISTRIBUTION OF ANIMALS.

A Text-Book of Zoogeography. By F. E. Beddard, M.A., F.R.S. Cambridge Natural Science Manuals. Pp. viii. and 246. Cambridge: University Press, 1895.)

WITHIN the small limits of 246 duodecimo pages of fairly large type, it is scarcely possible to do justice to such an extensive subject as the geographical distribution of animals; and, bearing in mind the difficulties thus imposed upon him, we think the author of the volume before us is, on the whole, to be congratulated on the manner in which he has completed a very difficult task. He has given the student a large amount of very valuable information, and this in a pleasantly-written and easily-understood form. A writer who was not thoroughly at home in his subject might have contented himself with merely giving us abstracts of Mr. Wallace's works, with such corrections as are necessary in order to bring them up to date. Not so Mr. Beddard, who has introduced into his text-book a very large number of facts, chiefly relating to the lower vertebrates and invertebrates, which are not to be found in more pretentious works, and his volume will thus be of value to all students. As being one of the author's specialities, attention is strongly directed to the distribution of earth-worms; and the remarks concerning the curious relationship between the worms of Patagonia and those of Australia and New Zealand will be found specially interesting.

The general plan of the work is as follows. After defining locality and station, and pointing out the variability in the distributional areas of animals, the author takes a number of selected instances, drawn from very varied classes, of the distribution of particular groups. We have, for example, the range contrasted of such different animals as rheas, ibexes, gallinaceous birds, edentates, tortoises, batrachians, scorpions, planarians, and earth-worms. Having contrasted the differences presented by these groups, Mr. Beddard comes to the consideration of zoological regions; and here he concludes on the whole to adopt those of Messrs. Sclater and Wallace. "As a mere matter of convenience," he remarks, "it is immaterial whether we join Europe, Asia, and North America into one Holarctic region, or use the current terms of Nearctic and Palæarctic for the Old and New World divisions of this extensive tract." With all due deference, we submit that convenience has nothing whatever to do with the matter; and it is to be regretted that the author has not been bolder, and made a clean sweep of what is obsolete in our present system of zoological geography. He admits that mammals are, on the whole, the most satisfactory group on which to lay the foundations of the scheme; and yet he deliberately throws away Mr. Blanford's very excellent classification, in order to adopt one which obviously does not accord with the facts.

A want of boldness is, indeed, in our opinion, one of the most serious defects in the work, and we should have much liked to hear the author express, without reservation, his real opinions both as regards the so-called Antarctica, and also in respect to Dr. Baur's view that the Galapagos Islands are part of a sunken continent. We gather that, on the whole, Mr. Beddard appears to be indisposed to admit Antarctica in its entirety, but as to how much he believes in a southern land connection of more limited extent, it is almost impossible to discover. In this section of the work, moreover, the author has made two glaringly contradictory statements. Thus whereas on page 116, in treating of the limits of the Australian region, he remarks that "the boundary between it and the Oriental is sharply marked," we find him on page 106 hesitating whether Celebes should not be transferred from the former to the latter region. So much for sharp boundaries.

The third chapter deals with the causes influencing distribution; and here it may be noted that the author differs from Dr. C. H. Merriam,[1] in that he attributes a very minor part to the influence of temperature. Not improbably, however, the difference of opinion is largely due to the different environment of the two workers, the effects of this factor being apparently more noticeable in the New World than in the Old. Very many interesting instances bearing on the problem of dispersal will be found in this chapter. In the fourth chapter, the faunas of islands are discussed; while the fifth closes the work with a few theoretical considerations. In this chapter we find the remarkable suggestion that Marsupials have taken their origin in Australia; a conclusion which, in our opinion, has no shadow of justification from the facts of their past history, and which is absolutely contradicted by the author himself. After stating on page 226, that their "number in Europe may have been small," he speaks of these animals on page 227 as "once existing in great variety in Europe and North America," and later on in the same page that the "survivors have been pushed in to the furthest corner of the world—the Australian continent, and some of the islands to the north." More hopelessly contradictory statements it would be difficult to find. As to the author's conclusions that there has been a general migration of the older forms from north to south, we are in full accord.

It is much to be regretted, especially from the point of view of elementary students, that the work should be disfigured by several glaring inaccuracies which ought to have been corrected in proof. We find, for instance, the genus *Anurosorex* given as exclusively Palæarctic, whereas one of the two known species is from Assam. On the same page, again, the genus *Capra* is likewise given as confined to the Palæarctic region, whereas, on p. 22, the South Indian *C. hylocrius* is included in the same genus. Should Mr. O. Thomas ever read the work, he will be surprised to learn (p. 90) that he has identified the African pouched rats of the genus *Cricetomys* with the American *Hesperomys*. On p. 97 we have "musk-deer" in place of "musk-ox"; while on p. 100 we find the Siberian hippopotamus figuring as *Chœropotamus* (the name of an Eocene genus of pigs) instead of *Chœropsis*. Again, on p. 103, we have the langurs alluded to under the name of *Presbytes*, while on p. 106 they appear as *Semnopithecus*. By what confusion of ideas the name *Hyracodon* (which belongs to an extinct genus of rhinoceros-like animals) is made to do duty for *Didelphys*, we are at a loss to understand. Carelessness is likewise

[1] See *Nat. Geogr. Mag.*, vol. vi. pp. 229-238 (1894).

exhibited by the statement, on p. 111, that *Rhea* is exclusively confined to the Chilian sub-region of South America, especially after the author has stated on p. 20 that *Rhea macrorhyncha* occurs in Pernambuco and Bahia.

As likely to mislead the student, we must also call attention to the so-called genera *Aquias* and *Phyllotis* being placed among those characteristic of the Oriental region, whereas Dr. Dobson,[1] whose views are endorsed by Mr. Blanford, states that there is no justification for the separation of the forms thus named from the ordinary *Rhinolophus*. If the author has reason to doubt the correctness of such generally accepted views, he should have appended a note to that effect. Many other points of this nature might be alluded to; but we cannot help regretting that the author has once more resuscitated the myth of the fossil Australian elephant.

While the book would have been much better had more care been exercised on its composition and correction, it will serve a useful purpose as a general guide to the principles of the geographical distribution of animals, and may accordingly be recommended to the student, provided he have sufficient knowledge to steer clear of the pitfalls.

R. LYDEKKER.

ALKALI MANUFACTURE.

A Theoretical and Practical Treatise on the Manufacture of Sulphuric Acid and Alkali, with the Collateral Branches. By George Lunge, Ph.D., Professor of Technical Chemistry at the Federal Polytechnic School, Zurich. Second edition, vol. ii. Pp. xi. 929. (London: Gurney and Jackson, 1895.)

TO criticise, in the ordinary sense of the term, such a book as this, demands an experience as wide as that of the author—not only in the laboratory investigation and the exposition of the problems of chemical technology, but in the exigencies of daily life in a chemical works. This dual experience is possessed by few, and the present writer can lay no claim to it. But the wide acceptance of the first edition of Dr. Lunge's book as *the* work of reference on alkali manufacture, makes the expression of a judgment on its value superfluous, and the reviewer need do little more than make a general comparison between the present volume and its predecessor of fifteen years ago.

It may at once be said that the book has been thoroughly brought up to date. It is bulkier than the former edition to the extent of over 200 pages, though many processes described in detail in the earlier work, being now obsolete, or nearly so, are here merely referred to; but though some of this increased bulk arises from lengthy detailed accounts of new processes, yet most of it is due to the small additions interpolated on almost every page of the book. No published work on alkali manufacture appears to have escaped Dr. Lunge, whether in journal or patent literature; and he has not only furnished an admirable digest of the progress made in technological thought and practice since 1880, but has throughout given references to original sources.

One change in arrangement commends itself at once: the modes of occurrence and properties of raw materials and products are collected in the first chapter, while analytical methods are similarly gathered together in the second. A striking feature in the first chapter is the amount of space devoted to native soda. Recent explorations have greatly extended our knowledge of the occurrence of this substance, and with sources of supply like Owen's Lake in California, it seems not at all unlikely that in a few years native soda may compete on a large scale with that manufactured by the Leblanc and the ammonia processes. The chapter on analytical methods is very complete, the chief new feature in it being the description and illustration of Lunge and Marchlewski's gas analysis apparatus on p. 113. It seems a pity that those who buy and sell alkali should not by this time have reformed the chaotic condition of "trade customs" which makes it necessary still to devote five pages of a work like this to the question of alkalimetric "degrees."

In the chapter on the salt-cake process the changes consist chiefly in the greater prominence given to plus-pressure furnaces, of which two forms are figured, and to mechanical furnaces. At the date of the first edition, plus-pressure furnaces were in little more than an experimental stage; but the advantages they present have gradually made themselves felt, and their use has become correspondingly more frequent. The early type of the Jones mechanical furnace has been omitted from this edition, and mechanical furnaces are represented by the later form of the Jones furnace, with fixed stirrers and movable bottom, by the Mactear furnace, and by Larkin's mechanical roaster. These furnaces are all fully described and figured, and the discussion of their merits and demerits is eminently fair. The account of the Hargreaves process has been completely rewritten and greatly improved, entirely new drawings of the arrangement of the cylinders having been introduced. That this beautiful process should not have further extended, is matter for regret; but, as Dr. Lunge justly says, it came too late—it has had to succumb to the competition of the ammonia soda process, and the consequent necessary subordination of other considerations to the production, in the Leblanc process, of strong hydrochloric acid.

The condensation of hydrochloric acid had reached such a stage at the date of publication of the first edition, that we find but few changes in this one, and but two noticeable additions: an account and discussion of Dr. Hurter's mathematical treatment of condensation, and a description of the Lunge-Rohrmann plate-columns. The gist of Dr. Hurter's papers is, on the whole, very faithfully reproduced; but there are two errors which are likely to cause confusion to the reader unacquainted with the originals: on p. 308, lines 6 to 10, where the source of the figure 43·3 is not obvious, the fact being that it is quoted from a third example of Hurter's, in which the gas dealt with contains 43·3 per cent. of hydrochloric acid; and on p. 313, where, in converting Dr. Hurter's English measures into metric units, 20 cubic feet per second is taken as 20 feet per second, and the resulting contact figure is worked out to 324 instead of 3474. The Lunge towers are described in the body of the work, and details of their structure, as well as a summary of results obtained in their actual working at Duisburg, are given in the addenda. These figures are certainly remarkable testi-

[1] Cat. Chiroptera Brit. Mus., p. [illegible].

mony to the efficiency of the plate-columns; whether in all respects they will achieve the results their inventor claims for them, it is, perhaps, yet premature to say.

The chapters on the black ash process, on the manufacture of finished soda, and on caustic, are examples of what has been said above as to Dr. Lunge's care and industry; exhibiting no striking changes, they are yet charged with additional matter, of which no satisfactory account can be given, but which will become continually evident to those using the book.

The recovery of sulphur from tank waste is, of course, treated at length. The multitude of attempts to solve this problem, the repeated failures—chemical or economic—of these attempts, the apparent hopelessness of further discovery in so well-explored a field, and the tenacity with which the attack has been continued, form one of the most interesting chapters in the history of manufacturing chemistry, and the account given here is full and accurate. Though the detailed description of Schaffner and Helbig's process has been omitted from this edition, yet the bulk has swelled by some forty pages, an increase due, of course, chiefly to the Chance-Claus process, the account of which, with its modifications and variations, is one of the best written portions of the book. How far this beautiful process affords a satisfactory solution of the problem of sulphur-recovery, may be gleaned from the fact that in 1893 the produce of Chance sulphur in Britain was estimated at 35,000 tons.

An indication of the tendency of chemical manufacture to become more scientific, to be guided by principles rather than by rule-of-thumb, is found in the increased amount of "theory" in the book. Not only have we accounts of investigations into the reactions involved in the various processes, but also accounts of the thermochemistry of the Hargreaves process and the black ash process, and of Dr. Hurter's application of mathematics to technology, mentioned above. No one will dispute Dr. Lunge's statement that manufacturing conditions are complex, and difficult to imitate in laboratory experiments, still more to state in a form definite enough for mathematical expression: no one will question the justness of his warning against proceeding too rashly on lines suggested by theory alone, or indicated by mathematical reasonings on insufficient bases; but the fact that thermochemistry and mathematics find a place at all in such a work as this, shows that our manufactures are being conducted with a closer knowledge than formerly of the principles—chemical, physical, and mechanical—which underlie them, and that we may look forward to a time when we shall have as full control over the conditions of our operations in the manufactory as we now have in the laboratory.

The Leblanc soda process is regarded, by those who are in any way connected with it, with feelings akin to those with which they look on the British Constitution. It inspires a certain affectionate respect, from its combined familiarity and antiquity; and the contemplation of its decay or extinction gives rise to feelings of regret, apart altogether from the pecuniary interests which are involved in it. The statistics given by Dr. Lunge, which show a steady increase in the salt used for the ammonia process, from 27,000 tons in 1880, to 350,000 in 1895, while that used for the Leblanc process has decreased in the same period from 650,000 to 470,000, are not reassuring; but if the older process be doomed to ultimate extinction it will at least have a worthy monument and history in the successive editions of Dr. Lunge's book.

Misprints and slips in such a work are inevitable; there are several, but nearly all such as betray themselves at once, and carry their corrections on their faces. A copious index to the volume adds greatly to its value for reference.

J. T. Dunn.

PHYSICAL ANALOGUES OF PROTOPLASMIC MOVEMENT.

Microscopic Foam and Protoplasm. By Otto Bütschli. Translated by E. A. Minchin. (London: Black, 1894.)

PROF. BÜTSCHLI'S work on Microscopic Foams has been already discussed in these columns; and therefore, in noticing the English translation, a very short account of the book itself will suffice. From his long series of observations, especially upon the structure of the protozoa, the author was led to regard protoplasm as a substance arranged always in the manner of an exceedingly minute honeycomb, containing a second substance in its cells. Taking this view of the structure of protoplasm, and probably stimulated by the experiments upon capillarity and surface-tension made by his colleague Prof. Quincke, he next endeavoured to find a substance having an analogous physical structure, and to produce in it some of the simpler phenomena of protoplasmic movement. The result was the manufacture of the remarkable foams, now so well known in zoological laboratories, in which the walls of the protoplasmic honeycomb are represented by thin laminæ of olive oil, the chambers containing a solution of potassium carbonate and soap. The remarkable resemblance between the histological structure exhibited by drops of this substance, and that of an amœba, is probably familiar by this time to most biologists, as is the resemblance between the streaming movements of the two structures, and the protrusion and retraction of pseudopodia by each.

In the work before us, the final investigations upon oil-foams are first described. The first eighty pages contain a minute description of the manner in which the foams are best prepared, and of their behaviour under the influence of various agencies. Especially interesting is the effect of induction shocks, by which convulsive movements are obtained, and the streaming is frequently slowed down or depressed. It is difficult to avoid comparing the manner in which such a foam-drop flows towards a solution of certain substances, such as soap, with the simpler phenomena of "chemiotaxic" attraction.

After a detailed description of the preparation and behaviour of oil-foams follows a summary of investigations on the structure of protoplasm, as seen in the living condition and after various methods of preparation. This account deals with the structure of various protozoa, and with the cells of many metazoon tissues, especially with nerve-cells and fibres; the object of the whole account being to demonstrate the "alveolar" structure of the protoplasm in all these cases. This account is illustrated by several plates, which have been admirably re-drawn for the English edition of the work, and in addition to these a collection of photographs has been prepared

illustrating the minute structure of oil-drops, and of many of the animal cells described. The evidence of this series of photographs is perhaps even more striking than that of the plates; and it is well here to draw special attention to them, because the only information given to the English reader as to the means of obtaining them is in a note on p. 341, where it may be easily overlooked.

The second part of the book contains a short history of the views which have been held concerning the structure of protoplasm, from the time of Remak's early observations on nerve-fibres until the year 1892; this is followed by a full exposition of the view that all protoplasm has the foamy structure exhibited by the oil-foams already described, and by a discussion of the difficulties which attend the explanation of all protoplasmic movement by reference to changes in the surface tension of a foamy substance.

Such is the arrangement of a work containing the most remarkable attempt to express protoplasmic movement in terms of inorganic phenomena which has yet been made. That the attempt is not yet successful in a number of special cases, Prof. Butschli himself is careful to point out; and the difficulty of explaining in this way the formation of fine thread-like pseudopodia is, as he admits, very great. A more serious difficulty, even in cases of simple lobose motion, is the difficulty of demonstrating those currents in the water outside an amœba in motion, which should, on the diffusion-theory, exist. These and other points are clearly stated by Prof. Butschli, so as to inspire the hope that the final section of his book will lead to the prosecution by himself and his pupils, and by others, of further work on the lines he has here laid down. Without such investigation, any detailed criticism of the difficulties would be simply impertinent.

Mr. Minchin is to be congratulated on his translation. The original German, while always lucid, is often difficult to translate, because the author has throughout been influenced on the one hand by a desire to be as brief as possible, and on the other by a spirit of scientific caution; so that he qualifies statement after statement with epithets which make his sentences easy enough to understand, but hard to render into such English as Mr. Minchin has generally achieved.

By incorporating the appendix of the original edition in the body of the work, a distinct advantage has been gained; and a useful feature, wanting in the German edition, is a very excellent index.

OUR BOOK SHELF.

Æsthetic Principles. By Henry Rutgers Marshall, M.A. (New York and London: Macmillan, 1895.)

MR. MARSHALL has done such good work in the field of æsthetics that we are glad to welcome this short and simplified exposition of the principles which he regards as fundamental. As we said on reviewing his more technical treatise, there is good stuff in his work, and it is based on right lines. We have only space to deal very briefly with one or two points on which we are still constrained to assume a somewhat critical attitude.

Although the view that pleasure is the accompaniment of the using up of surplus stored energy, and that pain arises when the stimulus calls for an overdraught of energy, may well hold good in certain fields of activity, it does not appear to touch some of the pleasures and pains of special sense. That certain groups of sensory stimuli are pleasurable, and others painful, seems just as primary and inexplicable (and therefore to be at present treated merely descriptively) as that certain light-vibrations give rise to the sensation blue, and others to the sensation red. They are primary data of "algedonics," as the colour-sensations are primary data of colour-vision.

In the helpful classification of "Instinct-feelings," so-called, we think more stress is laid on heredity than the facts at present justify. That there is an innate inherited potentiality of fear, for example, is unquestionable; and that it is connected with a tendency to flee from a disadvantageous object, may be admitted. But the disadvantageous nature of the object would seem to be a matter of individual experience, aided by the effects of what Mr. Hudson terms tradition through parents or others. It is at least questionable whether the advantageous or disadvantageous nature of the object is "determined by the experience of untold generations of ancestry."

The third, and last, point on which we would touch is the delimitation of the æsthetic field. That what is judged to be æsthetic appears to be permanently pleasant in revival may be, and in the main is, true enough. But that the relative permanence of the pleasure-field can be regarded as a sufficient æsthetic differentia, we are not prepared to admit. We cannot here discuss the question; we hold, however, that just as the pleasures and pains of sense on the algedonic accompaniments of sense-experience, so are the distinctively æsthetic pleasures and pains the algedonic accompaniments of the perception of relations. Mr. Marshall's criticisms of the intellectualist position (if this view of the purely algedonic accompaniment of activities, which in their cognitive aspect are intellectual, may be included under this head) is insufficient to carry conviction.

We have selected one or two points on which Mr. Marshall's views do not appear to us to be convincing; but it is partly because he is really worth differing from, that we can recommend his work for careful and serious consideration.

An Analysis of Astronomical Motion. By Henry Pratt, M.D. (London: G. Norman and Son, 1895.)

THE present small volume is a contribution to the ever-increasing mass of pseudo-scientific literature, in dealing with which a scientific reviewer must always find a difficulty. His first impulse is to ignore such a book altogether, but there are objections to such a course. To preserve strict silence might, in the first place, lead the author, and those who blindly trust his guidance to claim that his work was of real scientific value, since it had been tacitly accepted by the scientific world, or, at least, that his theory could not be confronted by any fatal *à priori* objections. Further, a book of this kind is liable to lead astray the untrained minds of chance readers, and one's duty to the public requires that some effort should be made to prevent the waste of time and money over an ignorant and worthless book.

Dr. Pratt's object in publishing the book is to give a simpler expression to the views developed in his earlier work, "Principia Nova Astronomica" (see NATURE, May 17, 1894). He may have found that students needed additional explanations, or that another advertisement was necessary to assist the sale of the earlier work. If the course were prompted by the first suggestion, one cannot say that the author has been altogether successful, for his theory remains quite as obscure and unsatisfactory as when first presented. The distinguishing feature of this theory requires our own sun to revolve round an "equatorial" sun, which in turn revolves round a "polar"

sun, which finally has its centre of motion in a "central" sun. "The evidence of the existence of the central, polar, and equatorial suns is found in certain observed phenomena, hitherto attributed to other causes, but which are in reality due to their presence and influence." Besides the simple enumeration of these phenomena, it is in vain to look for any direct proof of this statement. The author's method of removing objections to his theory, one of the principal objects of this book, is, however complicated in detail, extremely simple in principle. It practically consists in calling a motion, or an absence of motion, when it does not fit in and support his theory, *apparent*, and when such motion can be explained, or Dr. Pratt considers is explained, *real*. Such juggling with phenomena resulting from a combination of revolution and rotation, naturally presents no difficulty to a man who cannot see that a body revolving in an orbit, and always presenting the same face to the centre of the orbit, rotates once in the period of revolution. But others, taught in a different and more rigorous school, have great difficulty in apprehending the author's meaning, and fail altogether to appreciate the arguments by which he seeks to support the successive parts of his theoretical system.

Neither does Dr. Pratt understand the arguments, nor, as far as we can see, admit the facts, by which the gravitational theory is supported. In the third chapter, the author, in criticising our current ideas of planetary motion, discloses the awkward fact, that he has not the slightest acquaintance with Kepler's laws. He has not taken the trouble to master the first principles of the system he would overthrow, but seems to think himself qualified by inspiration to offer another. His inspiration, we fear, is due to a disordered and ill-regulated imagination.

The Physical Properties of Argon.

THE following measurements may be of interest in connection with the chemical position of argon. The gas was prepared from atmospheric air with the aid of oxygen and alkali only.

Weighings at 0° C. upon a large scale (two litres), and with the apparatus formerly employed for other gases, give as the density of argon ($O_2 = 16$)

$$19{\cdot}940,$$

a number in almost exact agreement with that obtained by Prof. Ramsay, working upon a relatively small scale and with gas derived by magnesium (Rayleigh and Ramsay, *Phil. Trans.*, 1895).

In spite of its greater density, the refraction ($\mu - 1$) of argon is only ·961 of that of air; so that if we take for air under standard conditions $\mu = 1{\cdot}0002923$, then for argon

$$\mu = 1{\cdot}000281.$$

Terling Place, July 20. RAYLEIGH.

The Teaching University for London.

I WAS absent from the country during the University of London Election; but I may be permitted to make a few remarks on Sir John Lubbock's letter in the last number of NATURE.

I am afraid he has hardly weighed the very serious consequences of the action he has taken. They will have to be met as best we may. What I now desire to consider is some of the grounds on which he has attempted to defend it. These themselves afford matter for sufficiently grave reflection.

(i.) Sir John states in his letter to Prof. Rucker: "I am not asking that any privilege which they do not at present possess should be conferred on my constituents, but only supporting what is now their legal right. . . . This right I know they highly value." This is a most extraordinary statement. What Convocation undoubtedly possesses is the right of veto on any fundamental change in the constitution of the University. It has been exercised in the past to some effect when Convocation summarily rejected the recommendations of the first of the recent Commissions. It might have been exercised when Convocation assented to the admission of women to the University. But it has never hitherto been exercised except by the personal vote of members attending Convocation who have had the opportunity of hearing in adequate debate the arguments for and against the proposal at issue. What Sir John proposes now is something widely different: a *referendum*, in fact, in which the decision of Convocation is to be signified "as at a Senatorial election," *i.e.* by voting papers. In my judgment such a precedent, if once established, would utterly destroy the prestige and authority of the meetings of Convocation as at present constituted. To this point I will return presently. But at any rate I think it will be admitted by all who know anything of the practical working of this body that Sir John's proposal is a pretty revolutionary change. How then are we to reconcile it with his language which I have quoted above.

(ii.) But Sir John's action becomes still more extraordinary in the light of the actual recent proceedings of Convocation itself. To read his letter it might be thought that we were smarting under a sense of injury and injustice, and that Sir John, as in duty bound, had come chivalrously to the rescue of our oppressed body. Far from this being the fact, I think, that in plain language Sir John has given Convocation the severest slap in the face it has ever received.

After the report of the first Commission was dead and buried, the second came up in due course for consideration by Convocation, and for the past two years its mind has been occupied with little else. The report might have succumbed to the veto like its predecessor, but it did not. I need not recapitulate all that has happened. It is enough to say that though Convocation approached the conclusions of the Commission with a certain timidity or, at any rate, reserve, their substantial acceptance after each successive debate steadily gained ground.

Finally at the meeting on January 22 of the present year the following resolution was carried:—

"That Convocation, while desiring to express generally its approval of the proposals contained in the Report of the Royal Commission, is of opinion that power ought to be given to the Statutory Commission to vary the details of the scheme, and that it ought to be made an instruction to the Commissioners, before framing the statutes and regulations, to confer with duly accredited representatives of the Senate and of Convocation, as to the modifications which may be desirable."

Now whatever be the opinion of different sections of Convocation on the general merits of the question, I think that we are all agreed as to the latter part of the resolution. Convocation regards the Report as a possible basis for reconstruction, but declines to pledge itself to all the details. But it is most important to observe, and it was most clearly pointed out in the debate, that in adopting this resolution Convocation *waived its right of veto*. In other words it dropped its possible *non possumus* and looked to negotiation to attain what it wanted.

This resolution was followed by a further one, which was its necessary executive corollary. I may be permitted to extract the whole from the minutes, as it is significant to observe that it was moved and seconded by a representative of either side.

"On the motion of S. P. Thompson, D.Sc., B.A., seconded by T. B. Napier, LL.D. Resolved:—

"(1) That a Special Committee of nine members, including the Chairman of Convocation, be nominated to prepare for presentation to the Statutory Commission, when appointed, a memorandum of points in the Scheme of the Royal Commission in which modification is desirable, and with power to confer with such said Statutory Commission, and with any Committee of the Senate.

"(2) That this Special Committee consist of the following Members: The Chairman of Convocation, Dr. Allchin, Mr. Bompas, Mr. Stanley Boyd, Dr. Cave, Mr. Cozens-Hardy, Mr. Thiselton-Dyer, Dr. Napier, Dr. S. P. Thompson."

Now I put it to Sir John, who, though I am glad to say not "an old," is certainly an experienced "parliamentary hand," whether the action he has taken is exactly courteous to Convocation in general or to its formally constituted Committee in particular.

What Sir John practically says to us is this: "You may do as you like, but I am taking the management of this business into my own hands." Now, we are undoubtedly proud of having a representative in Parliament; but I am very doubtful whether Convocation is prepared to accept that representative as its master.

The resolution of January 22, as it happened, owing to the prolongation of the debate, was not carried by a large majority. The question was therefore brought up again on May 14, and reaffirmed by more than two to one.

The present position then is this: Convocation has accepted the Report of the Commission in principle; awaits the appointment of the Statutory Commission; and has delegated to a Committee of men representative of various views the duty of conferring with it. This Committee, which has already held a preliminary meeting, can be in touch at any time with Convocation, and it is difficult to see what better machinery Convocation could provide to bring about the result which all reasonable men desire. And all this, Sir John, who is not a member of Convocation, and who has not apparently taken the trouble to acquaint himself with its proceedings, calmly sets aside for a new-fangled and unheard-of plan of his own.

(iii.) Sir John, in what I suppose I may call his defence, says "the University is the only body whose constitution it is proposed to change." I do not know, I am sure, how he arrives at this. But we, who have had to consider the point, have been advised very differently. It has been pointed out to us by very high legal authority, that some at least of the bodies which it is desirable to bring into closer co-operation with the University may be impeded by disabling enactments. And one of the strongest arguments brought before us in favour of a Statutory Commission was the fact that it is a legislative solvent, and could, subject of course to the approval of Parliament, remove any legislative impediment which stood in the way of its ordinances.

(iv.) What I have stated above is sufficient, I hope, to show that Sir John's interference really amounts to a grave invasion of the privileges of Convocation, and I am utterly at a loss to see by what considerations it can be justified. The principle of a *referendum* which it is proposed to force upon us, is one which can only be accepted after the most serious examination.

Let us consider what it involves. At present, on any question of moment, Convocation only proceeds to a decision after a prolonged debate. And I venture to say that in ability, and certainly in earnestness, the debates in Burlington Gardens will compare not unfavourably with those at Westminster. The divisions, it may be inferred, are the outcome of reasoned conviction. A *referendum* is a very different matter. It is only theoretically applicable when the issue is of the sharpest, and can be stated on the most explicit terms. For anything short of this it would be necessary to organise for and against any proposal a costly machinery in order to put before each voter a reasoned statement on one side or the other. But the Statutory Commission, from the nature of things, will have to deal with matters of the most delicate compromise, affecting, as I have shown, other institutions besides the University. To subject these to the accidents of a *referendum*, is, I venture to say, one of the maddest political expedients ever proposed.

I cannot refrain from adding one more remark. I deeply regret that Sir John, in addressing the President and other Fellows of the Royal Society, thought it worth while to point out to them that some of them were not his constituents. There are many students of practical politics who find it difficult to justify the existence of University Members at all. I take it that the only defence that can be made for them is that they are something more than the mandatories of merely local interests, such as may exist, say, in a borough. They stand in Parliament, if they have any claim to be there at all, as the representatives of those interests remote from party which ennoble and dignify the life of a nation. Universities may select and return such Members. But that duty performed, theirs begins. If Sir John really seriously thinks that it is inappropriate that a body of Fellows of the Royal Society should address the Member for the University of London on a matter of supreme public interest, then I can only say with the deepest regret that I hope that the day is not distant when our choice may fall on a man of larger sympathies with the interests of the higher education and learning.

W. T. Thiselton-Dyer.

Kew, July 20.

P.S.—I think it important to add from the Bill a portion of Clause 3.—"(1) The Commissioners shall make statutes and ordinances for the University of London in general accordance with the scheme of the report hereinbefore referred to, but subject to any modifications which may appear to them expedient after considering any representations made to them by the Senate or Convocation of the University of London, or by any other body or persons affected." It will be seen (i.) that it practically accepts the procedure of Convocation and (ii.) gives a *locus standi* to other bodies beside the University which may be affected.—W. T. T. D.

Sir John Lubbock seems to have a mistaken conception of the nature of the right of veto possessed by the Convocation of the University of London. The Charter of that University provides that Convocation shall have "the power of accepting any new or supplemental Charter for the University or consenting to the surrender of this our Charter." But such provisions cannot limit the action of Parliament. The provision is similar to the reference to Convocation at both Oxford and Cambridge of new statutes and of all alterations in old statutes proposed by the Council of the University. Our statutes take the place of the Charter of the University of London in many respects.

When Parliament has overhauled the Universities of Oxford and Cambridge by means of a Royal Commission, it has never occurred to any one that it would be proper to refer the statutes proposed by such Commission to the Convocation of Oxford or Cambridge. Sir John Lubbock's proposal to do what is parallel to this in the case of the University of London is a new departure. Whether he is aware of the customary procedure in dealing with universities, and thinks it objectionable, or whether he supposes that the plan he suggests is according to precedent, or, again, whether he is merely anxious to claim for his constituents an exceptional privilege by demanding which he will be giving effect to their wishes and justifying their selection of him as Parliamentary representative, does not appear.

For my own part, though not a graduate of the University of London, I have been most closely associated with its work and organisation—as professor in University College and as examiner in the University during twenty years. My conviction is that there is a large body of graduates, members of Convocation, who do not at all approve of Sir John's too flattering claim on their behalf; they do not desire that the Convocation of London should be given exceptional powers possessed by no other body of University graduates in this or any country. They are deeply concerned for the progress and development of the University of London in its true character of the University in the greatest city in the greatest empire of the world. And they are prepared to forego the gratification of personal vanity offered by Sir John Lubbock, in order that an executive Commission may carry out without delay the important development of the University proposed by the Gresham Commission. These proposals have been already approved of by a majority of voters in meetings of Convocation at which they were considered and discussed; the plan of again submitting the matter to Convocation after a Statutory Commission has embodied the Gresham Commissioners' proposals in detailed enactments, is one which can have no other object than that of defeating or, at any rate, delaying the whole scheme.

Sir John Lubbock has adopted, and made himself the leader of this extraordinary and fantastic policy. It seems to me that he has by his action shown an unfavourable estimate of the intelligence of his constituents, and that the time may come when the Convocation of the University of London will require from its representative active co-operation in the task of organising the University, and single-minded devotion to the interests of science, learning, and education, together with attention to those interests in Parliament, in place of the empty flattery of an impossible proposal to confer on Convocation powers rendering the customary Parliamentary control of the University impossible.

E. Ray Lankester.

July 20.

Without entering into the vexed question of the Gresham scheme, will you allow me to explain, in a few words, the grounds on which so many of Sir John Lubbock's old friends and supporters join issue with him entirely on the attitude he has taken up in his letter to Dr. Foster.

We object to the proposed *referendum* to the graduates, and to the mode in which he suggests that it should be exercised.

First, as to the mode. If Sir John Lubbock insists on the maintenance of the right of veto according to the Charter, this should clearly be exercised in the only method provided by the

Charter, that is, by Convocation assembled in a regular way. The constituency may be, as Sir John states, an exceptionally educated and intelligent one; but a very large proportion of the graduates have never studied the question of reorganisation, and are ignorant of its complications and difficulties. We have already had painful experience of how the votes of these graduates may be influenced by inaccurate or misleading statements in circulars issued through the post on the eve of an election by the party who are hostile to the Gresham scheme. If made in debate in Convocation, these statements could at once be corrected.

But, secondly, we object to the *referendum* in itself. Convocation has already, twice, deliberately, knowing what it was about, waived the right of final veto by agreeing to the appointment of a *Statutory* Commission. It maintains its full right of presenting its views to this Commission, when appointed, and of protesting against any provision that may interfere with its rights and privileges; and, furthermore, of influencing Parliament against it through its Member, or through any graduate who may have a seat in the House of Commons, or through its Chancellor, who sits in the House of Lords, should any such provision still be retained when the Bill is presented to Parliament. Any further right than this Convocation does not claim.

For my own part, should the position assumed by Sir John Lubbock be maintained by Parliament, it seems to me that we must abandon all hope of bringing our University into a line with the requirements of the age. ALFRED W. BENNETT.

The Earliest Magnetic Meridians.

IN reply to Prof. L. A. Bauer's letter in NATURE of July 18, p. 269, I may remark that I possess two of Churchman's Magnetic Atlases. The first of these I now believe was published in 1790, and to be that described in his tract, "An Explanation of the Magnetic Atlas, Philadelphia, 1790." The lines on this chart are magnetic meridians only, as fully defined in Churchman's text, and largely based upon Cook's observations of the variation.

It is evident that Churchman depended largely on observation, as he discussed the question of the effects of a ship's iron in altering the value of the variation when observed on board ship.

The second atlas, which is dated July 1, 1800, has isogonic lines for each degree of variation with magnetic meridians superposed, similar to Yeates' Chart of 1819, which I also possess.

Lastly, I would observe, that Yeates mentions the charts of Halley, Bellin, and Mountaine, and Dodson in 1794, but makes no reference to Churchman, who presented a copy of his work to the Royal Society in January 1791. It is possible, therefore, that Yeates constructed his chart in ignorance of Churchman's work, but the latter certainly was the first of the two to construct magnetic meridians. ETTRICK W. CREAK.

London, July 20.

Variegation in Flowers and Fruits.

REFERRING to a letter by Mr. Newnham Browne, in NATURE of July 11, describing a parti-coloured rose, it may be of interest to state that a somewhat similar occurrence in the case of an apple is recorded by Mr. Darwin in his "Animals and Plants under Domestication" (vol. i. pp. 392-3). The reference is to a specimen which I brought from Canada, and of which I sent him a careful drawing. In this specimen it appeared as if a smooth-skinned bright green apple had been cut in half and joined to a rough brown *pomme-gris*. The line of junction was perfectly sharp, but not quite symmetrical, the brown portion extending over the whole of the bud, while the green just included the stalk. I was told that similar instances sometimes were found on the tree from which it was gathered.

J. D. LA TOUCHE.

Stokesay Vicarage, Craven Arms, July 12.

Science Scholarships at Cambridge.

THOUGH the arrangements for the competitions for Science Scholarships at Cambridge, as described in NATURE of July 18, are in many respects eminently satisfactory, yet from the point of view of the candidates they leave something to be desired.

In the first place, they are unduly favourable to those whose nineteenth birthdays will fall early in 1896, and correspondingly unfavourable to those who are six or eight months younger. They will compel these younger candidates not only to compete at a marked disadvantage in the matter of age, but also after a shorter period of reading in science; unless, indeed, they have sacrificed an important part of their general education by commencing specialised study at an undesirably early age. Secondly, they are calculated to throw out altogether any candidates who may, through illness or other causes, be unable to compete during the very limited period covered by the examinations as at present arranged.

Similar difficulties are avoided in the case of the Army examinations by holding them twice yearly, at intervals of about six months. In the present case, sufficient equality could be secured by a fairly strong group of colleges holding their examinations a little later—for example, in April or May.

If it be feared that only the inferior candidates would be left to compete at this later examination, we would point out that, on the contrary, there would be less chance of this happening if our suggestion be adopted than under the present scheme. In April or May the older of the previously unsuccessful candidates would be excluded, and only the younger and, presumably, better candidates would remain. On the other hand, the later examination would have attractions for the ablest of those still younger candidates, who will not, under the present system, come into the field until the autumn of 1896. W. A. SHENSTONE.

Clifton College, July 23. D. RINTOUL.

SIR JOHN LUBBOCK AND THE TEACHING UNIVERSITY FOR LONDON.

THE feelings of "surprise and regret" which we said had been aroused by Sir John Lubbock's election address, will not be diminished by the perusal of the reply to which, at his request, we gave publicity in our last issue. Rather the surprise will turn to amazement, that he should deem that to be a reply which evades every material issue, and appears to be written in ignorance or forgetfulness of all that has taken place. And the regret will be enhanced when it is observed that his language now makes plain what could only be inferred from his address, namely, that he has never grasped the distinction between a Charter granted by the prerogative of the Crown, and a scheme framed under the authority of the Legislature.

Yet Sir John Lubbock has for many years taken an active, and even a prominent, part in public affairs; has for many years occupied a seat in Parliament; has in the course of his lifetime seen almost every university in the three kingdoms reformed by the machinery of Statutory Commissions; and has, if we are not mistaken, himself sat on a Commission entrusted by the Legislature with the duty of remodelling the constitution of the great public schools, which, next to the universities, are the most important educational institutions of the country. That he should be unaware of the distinction, or have forgotten it, seems incredible; but his language and his reasoning seem to leave no doubt on the point. "I am glad," he says, "to observe that the only point objected to is the reference of any new *Charter* to Convocation. In this, however, I am not asking that any privilege which they do not at present possess should be conferred on my constituents, but only supporting what is now their legal right."

What then, we are forced to ask, is Sir John's idea of a Statutory Commission? Does it need an Act of Parliament to authorise a body of persons to formulate proposals affecting a public corporation or institution, which, when framed, may be accepted or rejected at the pleasure of those whom they affect? Or does he suppose that it needs an Act of Parliament to enable the Crown to concur with bodies which the Charter of the Crown has called into existence, in effecting a modification of the franchise which they enjoy? An Act of Parliament, we had thought, was an Act of the Sovereign Legislature, which changed the "legal rights" as they previously existed; and we had never heard that Parliament added to its necessary labours the superfluous

task of passing Statutes to enable people to do what they had already the "legal right" of doing.

If this is Sir John Lubbock's view of a Statutory Commission, it was not the view taken by the late Royal Commission, to whose Report he indeed refers, but whose Report, we are compelled to believe, he has never read. For, in words too clear for misunderstanding, they have expressly recommended that the proposed change should be effected, "*not by Charter*, but by legislative authority."[1] Is it possible to suppose that in the discussions which have taken place in the Senate on the subject of the Report, the distinction so clearly pointed out has never been noticed or commented on in that august assembly, though presided over by the highest legal authority in the realm? Or if (as we must needs assume) the distinction did not pass unnoticed, was Sir John slumbering in his chair; and when he concurred in voting the resolution, by which the Senate accepted generally the recommendations of the Commissioners, including this vital one, was he not aware of the meaning of his act? Every assumption we make seems incredible; yet it looks as if, notwithstanding, some or one of them must be true.

The authors of the protest addressed to Sir John Lubbock say truly that it would be "without precedent" to confer on Convocation the right to "supervise the Acts of a Commission entrusted with the reorganisation of the University of which Convocation itself is a part." But when we ask ourselves how this right is to be exercised, the matter becomes not only unprecedented, but almost inconceivable. Is the ratification or veto of Convocation to be exercised directly on the Acts of the Statutory Commission, so as to be interposed between such Acts and the "approval of Parliament in the usual way," and so as to exclude Parliament from the power of considering any proposals of its own Commissioners not so ratified? Or is it to stand in lieu of the ratification of Parliament, so as to transfer the power of Parliament to the individual graduates? Or is the ratification of Parliament to be given only subject to the power of the graduates to disallow the Act of the Legislature? Or is, perhaps, the ratification and veto to be exercised by the more compendious method of entrusting the Member for the University with a power to overrule the decision of Parliament and its Commissioners? We shall look with interest at the particular form given to the clause which Sir John Lubbock proposes to introduce into the Bill.

But yet, for one so careful of the "legal right," one or two strange things are to be observed as to his proposal. Convocation, as we all know, has already, like the Senate, accepted the recommendations of the Commission, and, like the Senate, claims to represent its views before the Statutory Commission, when appointed. Convocation has passed this resolution in the exercise of its "legal right," and in the legal mode, that is, in the mode prescribed by the Charter on which alone its rights depend.[2]

[1] "In view of the failure of previous attempts to settle this question, and of the [illegible] and delay which must inevitably attend an alteration of the constitution of the University through the action of the University itself, we are of opinion that in accordance with the precedents followed in other cases of University reform, the change we recommend should be effected not by [illegible], but by legislative authority, and by the appointment of a Commission with statutory powers to settle, in the first instance, arrangements and [illegible] in general conformity with the recommendations which we are [illegible] to Your Majesty." (Report, p. [illegible].)

[2] The twenty-first clause of the Charter provides "That the Convocation of the University shall have the power following (that is to say):—The power [illegible] three persons for every Fellow to be appointed in the manner [illegible] [illegible] the power of [illegible] any matter [illegible] the opinion of Convocation [illegible] the power of accepting any new or supplemental Charter [illegible] ... (The italics are ours.)

Is it not a little strange, then, that this new power of ratification or veto, which is not an "existing legal right" at all, is to be exercised, not in the manner in which the acceptance of a new Charter is by the express language of the existing Charter to be exercised, but in a mode in which that very right, on the analogy of which the claim is based, cannot be exercised. But truly the argument is all of a piece; and the result is, that the individual graduate is to have a larger, and a more irresponsible, power in controlling the Acts of the Legislature, than he has in controlling the Acts of the Crown alone, acting on the instance of the Senate.

For, and this is the other strange thing, what in the view of this champion of "legal rights" is to become of the legal rights of the Senate? The Senate is the sole administrative governing body of the University. It is the Senate which must necessarily have the most intimate knowledge of the working of the system which it administers, and of the needs of the University for the conduct and reputation of which it is responsible. It is the Senate which would alone apply to the Crown for that new Charter which Convocation has the power of accepting or rejecting, and without whose application no such Charter would ever come under discussion. Surely it would be logical, or at least consistent in its illogicality, to require that the acts of the Statutory Commission should also be submitted to the approval of the Senate, and (let it be added) that the individual members of the Senate should record their opinion by means of voting papers. Or is it indeed only the "legal rights" of "constituents" that are to be, not indeed preserved, but extended by the creation of a new and exorbitant precedent?

POST-GRADUATE STUDY AND RESEARCH AT CAMBRIDGE.

THE Senate of the University of Cambridge have now approved new statutes for submission to Her Majesty in Council, conferring on the University the power of admitting to the degree of Bachelor of Arts, or Bachelor of Law, "advanced students" who have resided six terms, and have fulfilled certain requirements to be prescribed by ordinance from time to time.

The regulations which will become ordinances when the statutes are confirmed have been published, and run as follows. A few notes are added in square brackets by way of explanation.

Regulations for Courses of Advanced Study and Research.

(A) *Admission as Advanced Students of Persons who are not already Members of the University.*

(1) Applications for admission as advanced students shall be made to the Registrary.

No person shall be admitted as an advanced student who has not attained the age of twenty-one years.

(2) Each application shall be accompanied by

(i.) a diploma or other certificate of graduation at a University [British or foreign]:

(ii.) a statement as to the course or courses of (*a*) advanced study or (*b*) research which the applicant desires to pursue, together with such evidence of qualification, attainments, and previous study as he may be able to submit:

(iii.) a certificate or declaration that the applicant has attained the age of twenty-one years.

(3) In exceptional cases persons who do not present a diploma or certificate of graduation [at another University] may be admitted as advanced students, provided they give such evidence of special qualification as may be approved by the Degree Committee of the Special Board of Studies with which the proposed course of advanced study or research is most nearly connected.

(4) Applications shall, in general, be submitted not later than the first day of October in the academic year in which the applicant proposes to begin his course. But the authorities

specified in Regulation 5 shall have power to consider applications submitted at other times.

(5) The Registrary shall forthwith communicate each application to the Chairman of the Special Board of Studies with which the proposed course of advanced study or research appears to be most nearly connected.

Applications for admission to courses of advanced study shall be considered and decided upon by the Chairman of the Special Board.

Applications for admission to courses of research, and exceptional applications under Regulation 3, shall be considered and decided upon by the Degree Committee of the Special Board.

(6) The application shall not be granted unless it shall appear

(i.) that the course or courses of advanced study or research can conveniently be pursued within the University; and

(ii.) that the applicant has produced adequate evidence that he is qualified to enter upon the proposed course or courses.

(7) When the application has been decided, the Chairman shall inform the Registrary of the decision; and the Registrary shall inform the applicant.

(8) Before a person is admitted as an advanced student, he shall become a member of a College or Hostel, or a non-collegiate student [for this admission he must present satisfactory testimonials of character and attainments]. He shall not be allowed to count any term before that in which he has matriculated [by signing the matriculation book of the University, and paying a fee of £5: there is no "matriculation examination"], unless he has satisfied the Council of the Senate that his matriculation had been deferred for grave and sufficient cause.

(B) *Courses of Advanced Study.*

(9) An advanced student, who has kept two terms by residence, may in his third term of residence or in any subsequent term become a candidate for any of such Tripos examinations or parts of Tripos examinations as shall have been opened to advanced students under the provisions hereinafter contained.

The name of every such candidate shall be sent to the Registrary by the Prælector of his College or Hostel, or by the Censor of non-collegiate students, as the case may be, at the same time and in the same manner as the names of other candidates; but a mark shall be added to his name showing that he is an advanced student.

(10) It shall be the duty of each Special Board of Studies from time to time to consider whether the Tripos examination or a part only of the Tripos examination with which that Board is connected shall be open to advanced students, and also what standard in the examination must be attained by an advanced student in order that his name may be included in the list mentioned in the next Regulation: and their recommendation after approval by the General Board of Studies shall be submitted for adoption by Grace of the Senate.

In cases where two or more Special Boards are connected with a Tripos examination, the duty prescribed by this Regulation shall be performed by such Boards in joint meeting assembled.

(11) The names of such advanced students as satisfy the Examiners that they have attained the required standard in the examination shall be placed in alphabetical order on a list, written or printed, signed by all the Examiners and distinct from the Tripos list, which shall be regarded as the authoritative list and shall be preserved in the Registry. The Chairman of the Examiners shall send both to the Vice-Chancellor and to the Registrary a printed copy certified by him to be a correct copy of the authoritative list.

(12) An advanced student who has satisfied the Examiners as prescribed in Regulation 11 shall be qualified to enter upon a course of research, provided that the subject of his research be approved by the Degree Committee of one of the Special Boards.

(13) An advanced student who has satisfied the Examiners as prescribed in Regulation 11 and has kept by residence at least six terms shall be entitled to proceed to the degree of B.A. and thereafter under the usual conditions to the degree of M.A. and to other degrees in the University [*i.e.* for example, M.D., Sc.D., or Litt.D.].

(14) An advanced student who has satisfied the Examiners in the Law Tripos as prescribed in Regulation 11 and has kept by residence at least six terms, shall also be entitled to proceed to the degree of LL.B. and thereafter under the usual conditions to the degree of LL.M. and to other degrees in the University [for example, LL.D.].

(C) *Courses of Research.*

(15) An advanced student who has been admitted to a course of research shall pursue that course under such direction and supervision and under such other conditions as may be prescribed by the Degree Committee.

(16) An advanced student, who has kept two terms by residence, may in his third term of residence, or in any subsequent term, submit to the Degree Committee, not later than the division of the term, a dissertation containing an account of and embodying the results of his research. The dissertation shall be referred to one or more persons appointed by the Committee, who shall have power to examine the student orally or otherwise upon the subject thereof, and shall report thereon to the Committee. Each of the persons so appointed shall receive a fee of two guineas from the University Chest.

The Committee shall have power to take into consideration together with the dissertation any memoir or work [previously or subsequently] published by the student which he may desire to submit to them.

(17) If the Degree Committee be of opinion that the work submitted by the student is of distinction as an original contribution to learning or as a record of original research, they shall draw up a statement to this effect, indicating therein the subject or subjects of the student's research.

(18) The statement drawn up by the Degree Committee shall be forwarded by the Chairman to the Registrary, who shall embody it in a Certificate of Research in a form approved by the General Board of Studies. No such Certificate shall be granted unless and until three terms have been kept by residence.

Each candidate before receiving his Certificate of Research shall deposit in the University library a copy of his dissertation in a form approved by the Degree Committee.

(19) A student who has obtained a Certificate of Research and has kept by residence at least six terms shall be entitled to proceed to the degree of B.A. and thereafter, under the usual conditions to the degree of M.A. and to other degrees in the University [see Regulation 13, above].

(D) *Admission to Courses of Research of Persons who are already Graduates of the University.*

(20) A graduate of the University who desires to be admitted as an advanced student with a view to obtaining the Certificate of Research described in Regulation 18, shall make application to the Chairman of the Special Board of Studies with which his proposed course of research appears to be most nearly connected; and the application shall be considered and decided upon by the Degree Committee of the Special Board.

(21) The Degree Committee shall not grant the application unless they are satisfied

(i.) that the course or courses of research can conveniently be pursued within the University; and

(ii.) that the applicant has produced adequate evidence that he is qualified to enter upon the proposed course or courses.

(22) If the application be granted, the student shall become entitled to a Certificate of Research upon satisfying the requirements of Regulations 15–18.

(E) *Table of Fees for Matriculation, Examinations, and Degrees.*

	£	s.	d.
MATRICULATION.			
Advanced student (at any time, whether fellow-commoner or not)	5	0	0
[Certain Colleges, *e.g.* St. John's, Trinity, and King's, have recently admitted senior students, generally graduates of other Universities, as "fellow-commoners." These dine with the fellows, and have certain special privileges. Fellow-commoners not admitted as "advanced students" pay to the University a matriculation fee of ten guineas.]			
EXAMINATIONS.			
Advanced Students:			
On admission to a Tripos examination or a part of a Tripos examination ...	3	0	0
On submitting a dissertation for the Certificate of Research, on each occasion [*i.e.* the fee has to be paid again if the candidate is unsuccessful the first time]	5	0	0
DEGREES.			
Advanced Students:			
B.A. or LL.B. at any congregation for degrees	7	0	0

[The fee for these degrees, except at "general admissions," is ten guineas for students not admitted as "advanced students."]

Advanced students shall pay to the University Chest the same capitation tax as other members of the University, and under the same conditions as to standing (Graces June 1, 1893, and February 14, 1895); provided that the quarterly payment to be made by an advanced student, who has obtained a certificate of research but has not been admitted to a degree, and who has ceased to reside in the University, shall from and after the end of the eighth quarter from the commencement of residence be four shillings and threepence.

[The "capitation tax" referred to is thus in general ten shillings a quarter during the two years of residence, and four shillings and threepence a quarter thereafter until the advanced student removes his name from the boards of his College.]

The outcome of these regulations is this, that a graduate of a British, American, or other University, who can show evidence of special qualifications for advanced study in literature, law, history, or other like subject, or for scientific research, may be admitted under exceptionally favourable conditions to the University of Cambridge. He will not be required to pass the "previous examination" in Greek, Latin, elementary mathematics, and other subjects of preliminary education. He may reside two years instead of the three required of ordinary undergraduates. He will probably be allowed special privileges in respect of the University library, the museums, and the laboratories. He may become a candidate in the parts of certain of the Triposes concerned with his particular subject, or he may engage from the outset in independent research. If he approves himself sufficiently in the Tripos examination, or achieves results in relation to his research which may fairly claim "distinction," he may proceed to the degree of B.A. without further examination. Thereafter he need not reside further, but after the ordinary period of probation, pass to the higher degree of M.A. This opens the way to the doctorate in science or in letters for those whose after-work is of sufficient merit. A point of importance is contained in the second clause of Regulation 16, which provides that work published elsewhere may be taken into account in deciding whether an advanced student is qualified for his certificate or degree.

The "Degree Committee" of a Special Board consists of the professors and other elected members of the Board, but not the examiners for Triposes, &c., who are appointed for a year at a time. The special Boards deal respectively with theology, law, medicine, classics, oriental studies, mediaeval and modern languages, mathematics, physics and chemistry, biology and geology, history and archaeology, moral science, and music. The Triposes are the mathematical, classical, moral sciences, natural sciences, mechanical sciences, theological, law, historical, oriental languages, and mediaeval and modern languages. It has yet to be determined what parts of these shall be specially opened to advanced students, but as most of them are divided into two parts, it is likely that the second or more advanced and specialised parts will as a rule be made available. The University has made concessions as to the fees to be paid by advanced students, and there is no doubt that as the scheme comes into working order, the colleges will follow the lead of the University in this respect.

The scheme is one which should lead to important developments in the future. Graduates of other universities, whether they came from Oxford or Dublin, or were specially "attested," could share in the advantages which Cambridge has to offer, only on condition of becoming once more undergraduate students, and so beginning their academic course over again. Now, if they are sufficiently qualified by previous study and attainments, they are admissible on a higher and definitely recognised footing, and may at once enter on post-graduate work. It is to be hoped that, at least in English-speaking countries, the opportunities thus offered for higher study in Cambridge may soon be appreciated; and that a steadily increasing number of those who now from our colonies and the United States proceed to continental universities in pursuit of learning may find in one of the old English universities a more natural and a more interesting academic resort.

THE HEALTH OF LONDON.

THE immense strides which have been made in sanitary science, the well-nigh feverish eagerness with which all questions relating to health are pursued, causes the layman to turn with interest and, indeed, curiosity to any reliable record he can obtain of statistics relating to the public health.

"What," he asks, "is the actual practical result of all these efforts on the part of municipal authorities and other responsible public bodies on the health of our great cities?"

It is thus that statistics become invested with an interest even to the uninitiated, and there is no more striking tendency in the hygienic crusade which prevails than the sense of individual responsibility which it has succeeded in arousing in the conduct of sanitary matters, and the participation of the people themselves in measures of sanitary reform. Hence the compilation and issue by the London County Council of periodic reports on a variety of hygienic subjects; and the appearance of "County Council Orange Books" may now be regarded as a familiar feature in the administration of that democratic body.

One of the most recent of these is the annual report of the London County Council's Medical Officer of Health for the year 1893.

This weighty document bristles with figures, and embraces a variety of subjects, but to only a few of the more important of these can we briefly refer here.

Perhaps the most appropriate point to start from, is the consideration of some interesting data dealing with the *expectation of life*, actuarily calculated, enjoyed by Londoners from five years upwards in the period of 1881–90 and 1861–70 respectively.

These statistics go to show that the expectation of life of males at five years of age has improved from 47·49 years to 50·77; or, in other words, during the last period there has been a gain of 3·28 years. As regards females, we find the expectation of life has risen from 50·87 to 54·43, or a gain of 3·55 years. At subsequent ages there is also, in all cases, an improvement, though relatively less than at age five, showing that the greater part of the gain is in the periods of youth and early maturity.

If we compare these tables with those of a similar nature, which have been compiled for each sex in Manchester and Glasgow from 1881–90, we find that the expectation of life in London exceeds that enjoyed by the inhabitants of both these large cities.

Londoners may also congratulate themselves upon the fact that the death-rate in London was lower than that of the majority of the capitals of Europe and of New York; thus, we can contrast a death-rate of 21·3 per 1000, with 21·8 in Paris, 22·3 in Rome, 24·0 in Vienna, and 30·6 in St. Petersburg, and in New York 23·9 per 1000.

As compared with our five largest cities—Manchester, Liverpool, Birmingham, Leeds, and Sheffield—London again can boast of the lowest death-rate; whilst our infant mortality, compared with that of other English towns having more than 200,000 inhabitants, was also lower in every case with the single exception of Bristol.

If we look more closely into the particulars of the death rate, we find that, as regards the principal zymotic

diseases, London shows an increased mortality over the average for the preceding ten years, the rate having risen from 2·10 to 2·28 per 1000; and although this zymotic death-rate compares favourably with that of the largest of our towns, yet as regards foreign capitals it is only exceeded in two cases, *i.e.* by that of Stockholm and Vienna.

This increase is largely due to the alarming rise which has taken place in deaths from diphtheria, a rise represented by a death-rate of 0·12 per 1000 in the years 1871–80, 0·26 in 1881–90, 0·31 in 1891, 0·44 in 1892, and, lastly, 0·74 in 1893. Such a diphtheria death-rate is markedly in excess of that of other large English towns having a population of more than 200,000, being, in fact, more than double that of any with the exception of West Ham (virtually a part of London); it was even ten times as great as the diphtheria death-rate of Nottingham, and six times as great as that of Liverpool.

Small-pox also appears to be on the increase, and influenza and pneumonia claimed a number of victims greatly in excess of the average of the preceding ten years; and there is, also, a substantial increase registered in the scarlet-fever death-rate.

But the most serious problem which we have to face is our diphtheria epidemic; various attempts have been made to ascertain to what it can be traced, but so far, it must be confessed, we are without any satisfactory clue as to its source. It has been attributed by some to alterations in the classification of diseases, more especially by transference to diphtheria of deaths which in former years were registered as croup, by others to increased facilities for the spread of infection afforded by increased school attendance, to sewer ventilators, &c.; but the fatal objection to all these explanations is that they are circumstances which are shared by all the other great cities and towns of the country, and yet London alone is pre-eminent in its death-rate from diphtheria.

There appears, however, to be a very decided tendency in England for diphtheria to increase in densely inhabited centres, whilst in the more sparsely populated districts there is a decrease, which has been especially emphasised of late years.

Curiously, this is not the experience of our neighbours in Germany. Dr. Hecker has quite recently conducted an elaborate inquiry into the diphtheria death-rate during the years 1883–93 in a number of German cities, and he states that it is a decreasing one.

The problem of diphtheria in London is as yet unsolved, neither is its solution likely to be accomplished through such isolated, individual investigations such as have hitherto prevailed. What is required is the appointment of a Commission, composed of men abreast of the time, acquainted with modern methods, and capable of pursuing experimentally, if necessary, the course of this scourge.

Fortunately, as regards cholera, our past experience has enabled us to cope satisfactorily with what was at one time our most dreaded foe, and although Europe has suffered severely, England has escaped since the outbreak of cholera in London in the year 1866.

The freedom of London from this, to a large extent, water-borne disease brings us to the consideration of another malady in the communicability of which water is also largely responsible, *i.e.* typhoid fever.

In this connection it is satisfactory to read the following: "A point well deserving of observation, is the diminishing London typhoid fever death-rate."

Although it cannot be assumed that it is entirely due to improvement in the water supply of London, yet the evidence of the connection between typhoid fever and impure water supplies, has been too firmly established not to permit of the London water companies obtaining some credit for this improved hygienic condition.

On this point, the evidence afforded by the city of Zürich is instructive, for it has been distinctly found that since the establishment of the new filtration works in 1886, and the consequent greatly improved bacterial quality of the water distributed, a very marked diminution has taken place in the number of cases of typhoid fever. This fact has been vouched for after most careful investigation of facts and statistics by the city authorities.

Again, we have only to recall the invariable increase in cases of typhoid fever in Paris, when in consequence of an insufficient supply of purer sources of water, recourse has to be had to that of polluted river Seine water. Now Dr. Percy Frankland, in his reports to the Local Government Board, showed, for the first time in this country, the bacterial purification which Thames water undergoes at the hands of the London water companies; and although in his recent report to the Royal Society on the vitality of the typhoid bacillus in various waters, he points out that, whilst unable to increase in numbers, it can yet remain alive for days and weeks in water, yet we may assume that the typhoid bacillus will submit, as all ordinary water microbes, to the purification processes which Thames water undergoes before delivery, processes which Dr. Percy Frankland has repeatedly shown, removes frequently as many as 99 per cent. of the bacteria present.

Under the heading of "Administration," we read that the Council's inspectors made numerous inspections of dairies and milk-shops, as well as cow-sheds; as a result of these investigations, no less than 133 cases of scarlet fever were discovered as occurring on milk-shop premises, 46 cases of diphtheria and membranous croup, 21 cases of typhoid fever, 10 cases of small-pox, 5 cases of erysipelas, and 2 cases of measles. These probably represent only a proportion of the actual number of cases which took place in such establishments. Knowing as we do that milk offers every facility for the growth and abundant multiplication of pathogenic germs, it may be easily conceived how much zymotic disease may have been disseminated broadcast from these centres of infection.

In the recent report issued by the Royal Commissioners on tuberculosis, we find the following significant paragraph: "In regard to milk, we are aware of the preference by English people for drinking cow's milk raw, a practice attended by danger on account of possible contamination by pathogenic organisms. The boiling of milk, even for a moment, would probably be sufficient to remove the very dangerous quality of tuberculous milk."

We quote these words in full, not only because of the official weight which attaches to them, but because it is of such great hygienic importance that these facts should be known and realised by the general public.

On the continent, the practice of drinking raw milk is fast becoming obsolete, and sterilised milk is an article of commerce, and successful so-called "milk sterilising associations" have been formed for its distribution.

We have seen that, as regards the zymotic-disease death-rate, London is less favourably situated than the majority of the capitals of Europe. May we not possibly find at least one cause of this, to us humiliating fact, in the insular prejudice which prevails in favour of raw milk?

In conclusion, valuable as statistics may be and undoubtedly are, it must be remembered that there is yet much which statistics cannot reveal, that a lower death-rate cannot express the whole result of hygienic enterprise and progress. To adequately measure the value of sanitary reform to the community at large, we must look as well to the numerous and important improvements which have resulted in the increased comfort and well-being of the individual, and it is in such directions that the London County Council has accomplished some of its most useful and meritorious work.

THE RECENT RACE OF AUTO-MOBILE CARRIAGES IN FRANCE.

LAST month a most interesting race of auto-mobile carriages took place in France. The course taken was from Versailles to Bordeaux, and then back to Paris. June 11 was fixed for the day of starting, and forty-six carriages were to have taken part in the race, but only twenty-eight arrived in time, twenty-two of these taking active part, and nine performing the journey within a hundred hours; eight of the latter were worked by petroleum or "gazoline," and one by steam.

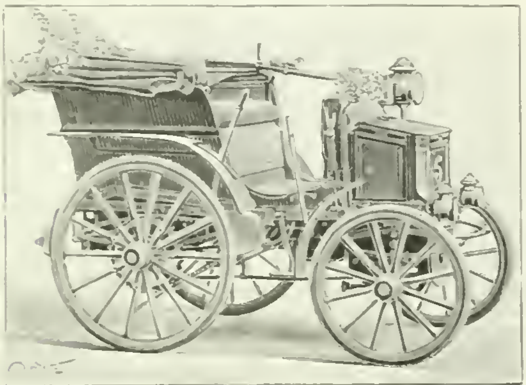

FIG. 1.—No. 5. MM. Panhard and Levassor's carriage, worked by gazoline, and seated for two persons (2nd prize, 12,000 francs). Arrived June 13, at [illegible]

The accompanying illustrations, which we are enabled to reproduce by the courtesy of the Editor of *La Nature*, are from photographs taken at the exhibition of the carriages on their return. No. 5 (Fig. 1) is the one which was the first to arrive back in Paris. It received the second prize, for it only seats two persons, and a regulation had been made, that no carriage seating less than four persons could receive the first. No. 16 (Fig. 2) reached Paris fourth, but received the first prize, for on reckoning up the time taken in the journey, it was found to be [illegible] less than that taken by No. 8. The third prize was won by No. 15 (Fig. 3).

FIG. 2.—No. 16. MM. Peugeot Frères, worked by gazoline, and [illegible] four persons (1st prize, [illegible] francs). Arrived June 14, at [illegible]

Taking all the facts into consideration, it appears that the lighter carriages travelled best. This proves the advantage of using petroleum or gazoline, for in order to produce one horse power it requires per hour $1\frac{1}{11}$ lbs. of gazoline, whereas, if it were worked by steam, at least $6\frac{3}{5}$ lbs. of coal and $39\frac{3}{5}$ lbs. of water would be necessary per hour, and if worked by electricity, there would have to be accumulators of the weight of 220 lbs.

Light carriages have many advantages, for besides having to be less careful about the weight of fuel, they can also have lighter constructed wheels. M. Michelin's carriage, with pneumatic tyres, went the whole distance without an accident, whereas the steam vehicles, one and all, had mishaps, owing almost always to their great weight.

It would take up much time and space to relate the many incidents which occurred; suffice it to say that, apart from ordinary breakdowns, in some towns the travellers were hindered by the inhabitants, in others they were enthusiastically pelted with flowers.

These auto-mobile machines are evidently the carriages of the future. According to the *Times* of July 10, a journey has quite recently been performed in our own country by the Hon. Evelyn Ellis, who was accompanied by Mr. T. R. Simms, managing director of the Daimler Motor Syndicate. The carriage is a four-wheeled dog-cart, and will hold four persons, with room also for two portmanteaus. It was built by Messrs. Panhard and Levassor, of Paris, and is worked by petroleum, the cost being about a halfpenny an hour. The journey undertaken by Mr. Ellis, a distance of fifty-six miles, was performed in five hours and a half.

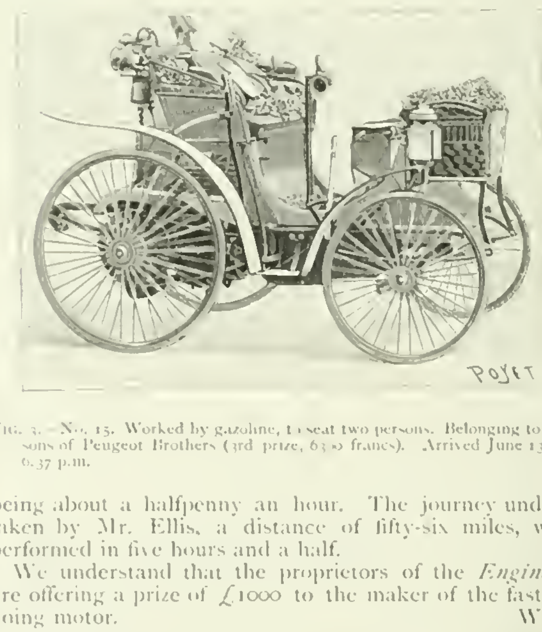

FIG. 3.—No. 15. Worked by gazoline, to seat two persons. Belonging to the sons of Peugeot Brothers (3rd prize, 6300 francs). Arrived June 13, at 6.37 p.m.

We understand that the proprietors of the *Engineer* are offering a prize of £1000 to the maker of the fastest going motor. W.

NOTES.

WE regret to notice that Prof. C. C. Babington, F.R.S., Professor of Botany in the University of Cambridge, died on Monday morning, at the age of eighty-six.

PROF. RAMSAY has been elected a Correspondant of the Paris Academy of Sciences, in the Section of Chemistry, and M. Sabatier has been elected a Correspondant of the Section of Anatomy and Zoology.

MR. H. J. CHANEY, of the Standards Department, Board of Trade, will attend the Sexennial Conference of the International Committee on Weights and Measures at Paris, on September 6 next, as the representative of Her Majesty's Government.

DR. CARL BARUS, of the Smithsonian Institution, has, says *Science*, accepted the Hazard Professorship of Physics in Brown University. It is stated that Brown University has recently spent £20,000 in the building and equipment of a physical laboratory.

THE death is announced of Prof. Baillon, Director of the Botanical Laboratory of the Faculty of Medicine at the Sorbonne. Prof. Baillon was one of the most distinguished of French botanists, and perhaps quite the most prolific author of works in that science of the last quarter of a century. The *Times* gives the following details of his life. He was born at Calais, November 30, 1827, and was destined for the medical profession. He prosecuted his studies at Paris, and soon obtained prizes for work in "L'École Pratique," and in the hospitals. In 1855 he received the double degree of doctor of medicine and of the natural sciences. In 1864 he was appointed Professor of Medical Natural History to the Faculty of Paris, and soon afterwards Professor of Hygiene to the Central School of Arts and Manufactures. He was decorated with the Légion d'Honneur on August 17, 1867, and promoted to Officer July 13, 1888. His chief publication was "Histoire des Plantes," a vast undertaking, in twelve fully-illustrated volumes, the publication of which commenced in 1866, and concluded only three years ago. It has been partly translated into English. His next great work was a "Dictionnaire de Botanique," which he begun in 1876; the first volume appeared in 1878, and the fourth in 1885. He also published a number of monographs and studies on various natural orders and groups of plants.

MR. W. N. MOORE has succeeded Prof. Mark W. Harrington as Chief of the U.S. Weather Bureau.

MR. O. A. L. PIHL, whose careful measurements of the stars in the cluster χ Persei are well known in astronomical circles, has just died at Christiania.

PROF. J. G. AGARDH has presented his fine collection of dried algæ to the University of Lund, on the condition that it remains there intact, and the specimens not be lent out.

MR. CHARLES LEIGH, assistant in the General Library of the Natural History Museum, South Kensington, has been appointed to the post of assistant secretary and librarian to the Manchester Literary and Philosophical Society, created under the Wilde Endowment Fund.

A SHARP earthquake shock was felt at Algiers at 11.25 on the night of Friday last, July 19. The direction of motion is said to have been from west to east.

THE National Herbarium of the United States at Washington has been transferred from the building of the Department of Agriculture, and now forms a part of the National Museum in the Smithsonian Institution. The collection of grasses remains, however, with the Department of Agriculture, as also do the collections of the Divisions of Vegetable Pathology and Forestry. A movement is now on foot among American botanists for providing the National Herbarium with a suitable building and a staff of scientific assistants.

THE adjudicators appointed under the provisions of the deed of settlement of the Daniel Hanbury Memorial Fund have, says the *Pharmaceutical Journal*, awarded the eighth Hanbury Gold Medal to Dr. August Vogl, Professor of Pharmacology and Pharmacognosy in the University of Vienna. The medal is awarded biennially for the prosecution or promotion of original work in the chemistry and natural history of drugs. On the last occasion, in 1893, it was awarded to the late Johann Michael Maisch, who received it just before his death.

THE following grants have been made by the Council of the Chemical Society on the recommendation of the Research Fund Committee:—£30 to Messrs. J. J. Hummel and A. G. Perkin, for the investigation of certain natural colouring matters. £10 to Dr. H. Ingle, for the purchase of various aldehydes, ketones, and hydrazine, to continue his work on stereoisomeric osazones. £10 to Dr. J. J. Sudborough, to continue his work on diortho-substituted benzoic acids. £15 to Mr. E. Haworth, for the synthesis of an acid having the composition $C_8H_{14}(COOH)_2$, and the comparison of its properties with those of camphoric acid. £5 to Mr. R. E. Doran, for a research on the preparation of mustard oils by the reaction of chlorocarbonic esters with lead thiocyanate. £15 to Dr. W. A. Bone, to continue a research on the substituted succinic acids, and on the behaviour of various trimethylene compounds on treatment with the sodium compound of ethylic malonate. £10 to Dr. B. Lean, to extend his work on the derivatives of ethylic butane tetracarboxylate. £20 to Dr. J. Walker, for an investigation of the conditions of equilibrium between the cyanates and the corresponding ureas.

MR. W. SAVILLE-KENT, who has recently returned from Western Australia, has presented and otherwise placed at the disposal of the Trustees of the British Museum a further collection of Madreporarian corals and sponges collected by him on the north-western coast-line of the above-named colony. The series includes many new species and specimens calculated to prove attractive exhibits in the public galleries. With this latest addition included, the Natural History Museum becomes possessed of the most complete collection of Australian Madreporaria that has yet been brought together, and which now comprises typical examples collected by the same authority from every region of the extensive coral-producing waters of the Australian continent. Mr. Saville-Kent will probably be engaged for the next few months in the compilation of a book dealing generally with the more interesting natural history observations and investigations he has recorded and prosecuted during the past ten years while holding the appointments of Commissioner of Fisheries to the several Governments of Queensland, Tasmania, and Western Australia.

BY the provisions of the will of the late Dr. William Johnson Walker, two prizes are annually offered by the Boston Society of Natural History for the best memoirs written in the English language on subjects proposed by a Committee appointed by the Council. For the best memoir presented, a prize of sixty dollars may be awarded; if, however, the memoir be one of marked merit, the amount may be increased to one hundred dollars, at the discretion of the Committee. For the next best memoir, a prize not exceeding fifty dollars may be awarded. The competition for these prizes is not restricted, but is open to all. Attention is especially called to the following points:—(1) In all cases the memoirs are to be based on a considerable body of original and unpublished work, accompanied by a general review of the literature of the subject. (2) Anything in the memoir which shall furnish proof of the identity of the author shall be considered as debarring the essay from competition. (3) Each memoir must be accompanied by a sealed envelope enclosing the author's name and superscribed with a motto corresponding to one borne by the manuscript, and must be in the hands of the Secretary on or before April 1 of the year for which the prize is offered. The subjects for 1896 are:—(1) A study of an area of schistose or foliated rocks in the eastern United States; (2) a study of the development of river valleys in some considerable area of folded or faulted Appalachian structure in Pennsylvania, Virginia, or Tennessee; (3) an experimental study of the effects of close-fertilisation in the case of some plant of short cycle; (4) contributions to our knowledge of the general morphology or the general physiology of any animal, except man. The subjects for 1897 are: (1) A study of glacial, fluviatile, or lacustrine phenomena associated with the closing stages of the glacial period; (2) original investigations in regard to the chalazal impregnation of any North American species of Angiosperms; (3) an experimental investigation in cytology; (4) a contribution to our knowledge of the morphology of the Bacteria.

REPORTS upon the circumstances attending an explosion which occurred in the Timsbury Colliery last February, prepared by Mr. J. Roskill and Mr. J. S. Martin, have just been published in a Blue Book. The explosion is interesting because fire-damp is practically unknown in the colliery. In this colliery, as throughout the Radstock series of the Somersetshire coalfield, naked lights are used; it is exempted from the application of the section of the Rule which prohibits explosives being taken down in mines except in cartridges, and gunpowder alone is used for blasting. It is evident from the inquiry that this exemption should be cancelled, and Mr. Roskill recommends that the use of gunpowder, except in cartridges, should be prohibited. Although before the explosion parts of the colliery were known to be dry, while more or less dust occurred in places, yet the mine was not regarded as a "dry and dusty mine." Judging from the explosion, however, the mine should come within that category. The explosion occurred at a spot which was apparently not dry and dusty within the meaning of the Act; but it was, if not caused, certainly intensified, by the presence of dust at much greater distances than twenty yards from the spot, though the Rule relating to shot-firing in a dry and dusty place, only prescribes watering within a radius of twenty yards. The moral drawn from the disaster is (1) that roburite, or one of the so-called flameless explosives, should, in future, be used instead of powder, and (2) that when places in a mine are admittedly dry and dusty, every place in the mine should be considered to be so, for the purpose of shot-firing, in order to make it imperative that, in such mines, the precautions prescribed by General Rule 12 should be observed in *all* places of firing.

WE have received a copy of the Report of the Epping Forest Committee presented to the Court of Common Council on June 13, of the present year, and containing the memorials which were reprinted in these columns a short time ago (June 13, p. 158). In presenting the Report the chairman, Mr. Deputy Halse, said that "if the action of your Committee were judged alone by the weight of authority attaching to those who have expressed themselves to be so entirely in accord with the past management of the Forest, a complete answer to the charges has already been made; but we prefer to await and present to your Honourable Court the Report of the eminent experts in Forestry whom we consulted last year, and by whose opinion and decision we are perfectly prepared to be judged and bound." We understand that the Committee of experts visited the Forest last week, and their judgment will be awaited with interest. Nothing could, however, strengthen the hands of the Committee more than the memorials which are now made public with their attached signatures. The value of the Report from a public point of view is greatly enhanced by a set of photographs reproduced from the illustrations in one of the daily papers, and placed opposite the views of the actual places which the newspaper artist is supposed to have represented. The article from the paper itself is reprinted *in extenso*, with a note stating that "the above article was accompanied by the illustrations reproduced on the annexed photographic sheet. Its accuracy may be judged from the photographs of those portions of the Forest supposed to be illustrated, which were taken within two days of the appearance of the article." The absurdity of the clamour, which is raised year after year by a small and irresponsible body of agitators, is well brought out by the article and its illustrations when confronted with the true representations. Any paper that lends itself in future to such perversions will justly forfeit public confidence. The keen interest taken by the people in the management of Epping Forest is a very healthy sign, but the case against the present Conservators must indeed have been feeble if it was found necessary to resort to such pictorial artifices as are exposed in the Report issued by the Common Council.

UNSETTLED weather has prevailed in most parts of the British Islands during the last week, and thunderstorms have occurred in various places, while falls of rain exceeding an inch in twenty-four hours have been recorded on several days. In London, there were two distinct thunderstorms on Sunday last, one of which, between two and three p.m., was accompanied by an exceptionally heavy fall of hail. The amount of rain in London on that day was about 1·3 inch, which is the heaviest fall in twenty-four hours since last October.

AT the recent meeting of the Australasian Association for the Advancement of Science at Brisbane, Mr. C. L. Wragge proposed the erection of a meteorological station on Mount Wellington, Hobart. The proposal was supported by Mr. H. C. Russell, Government Astronomer of New South Wales, and by the Royal Society of Tasmania, in consequence of which the Government voted the necessary funds. An experimental station has just been established by Mr. Wragge on the summit of the mountain at a height of 4166 feet above sea-level, and a permanent observatory-house is now in course of erection. There are also corresponding stations at the Springs (2495 feet), and at Hobart (160 feet); we have no doubt, therefore, that results of importance will be derived from them. Mount Wellington is about four miles distant from Hobart, in a straight line, and rises almost directly from the level of the sea: it consequently offers considerable advantages for meteorological research.

THE Pilot Chart of the North Atlantic Ocean for July contains monthly charts, representing graphically the regions where fog was experienced most frequently on the North Atlantic during 1894. As this year can be taken as a typical one to illustrate the distribution at different seasons, it is interesting to note that during the first three months of the year fog is experienced on the Grand Banks and to the westward, but not in large quantities. During April it begins to extend to the northward and eastward, increasing in frequency as the spring advances, and reaching its maximum, generally, in June or July, during which months it may be expected anywhere between the American coast and this country in large areas and of long duration. In August the fog begins to dissipate in the eastern part of the ocean, and in September the decrease is very perceptible. During the remaining three months the charts show that it reaches its minimum again, and is mostly restricted to the westward of 40° west longitude.

SOME brief telegrams in the daily papers announced the occurrence of an earthquake in the Meshed district of Persia on January 17, but gave little indication of its destructive character. The centre of the earthquake appears to have been near Kúchán, a town which has been damaged or destroyed by earthquakes several times during the present century, the last occasion being in 1893, when it was completely reduced to ruins. After this the town was rebuilt on the old site, but the houses were made very largely of wood. At the beginning of this year, the new town contained about 2000 houses and 8000 inhabitants. On January 17, shortly before noon, another disastrous earthquake occurred. It lasted about a minute, and the shock was so severe that it completely destroyed every house in the town, with the exception of a few small shanties. The wooden pillars of the better-built houses were all broken in the middle. Numbers of people were buried in the ruins, but, owing to the lightness of the materials, the loss of life was much less than it would otherwise have been. The local authorities estimated the number of deaths from two to six thousand, but the careful inquiries of an attaché at the British Consulate-General at Meshed have reduced this figure to about

700. Orders have been issued by the Persian Government for the town to be rebuilt near Hai Hai, a place six or seven miles to the south-east, which experience has shown to be safe from destructive shocks.

THE history of the Russian Biological Station, on the island of Solowetzk in the North Sea, has already been given in our columns (NATURE, November 1894, p. 83). One of the most interesting of the results achieved by the naturalists of the laboratory has been the discovery of a remarkable lake on the island of Kildine in the Arctic Ocean. This lake, which is completely separated from the sea by a narrow strip of land, was discovered by the Russian naturalist, M. Herzenstein, who was struck by finding in the lake a fish which is exclusively marine in habit, namely the common cod. Further observations by MM. Faussek and Knipowitsch have elucidated the peculiar features of the fauna of the lake. On the surface the water is fresh, and is inhabited by fresh-water animals, such as Daphnids, &c.; this water is brought to the lake by streams from a neighbouring marsh. Under the superficial layer of fresh water is found salt water, supporting a Marine fauna—Sponges, Sea-anemones, Nemertines, Polychætes, marine Molluscs (*Chiton*, *Æolis*, *Astarte*), Starfish, and Pantopods. There is even a regular littoral zone beneath the fresh water, characterised by small *Fuci*. The bottom of this lake is covered with mud exhaling an odour of sulphuretted hydrogen, and is not inhabited. The water of the lake shows a slight ebb and flow, attaining a vertical height of only a few inches, while the tides in the adjacent sea are considerably greater. This fact would appear to point to the existence of some subterranean communication between the lake and the sea.

SOME important additions to a knowledge of the latest Mesozoic and early Tertiary mammalia have recently been made from Patagonia and the Uinta Basin. From the former place a collection of ungulates of very late Cretaceous date is described by Señor F. Ameghin in the *Bol. Inst. Geografico Argentino*, t. xv., 11 and 12. The most important is a new genus, *Pyrotherium*, which is made the type of a new sub-order, regarded as ancestral to the Proboscidea, and showing marsupial affinities. A number of other new genera are also described, and it is anticipated that when the fossil localities, which are very difficult of access, have been more fully investigated, still more valuable information on the late Mesozoic mammalia will be obtained. Large Dinosaurs and birds also occur in these beds.

PROF. H. F. OSBORN reports in the *Bull. Amer. Mus. Nat. Hist.*, New York, vol. vii., art. 2, on a more extensive collection than has hitherto been obtained from the Eocene beds of the Uinta Basin. Beneath the true Uinta fauna comes one which is intermediate between it and the Bridger and Washakie faunas, and thus supplies a most important link in the faunal succession of this province, while at the same time it shows affinities to the Miocene fauna of the White River. Among the mammalia found in this transitional fauna are a monkey, and species of *Telmatotherium*, which definitely confirm the view that that genus was ancestral to the Titanotheria. It is expected that still more valuable results may be got from a more thorough exploration that is being made this year.

THE application of electricity to locomotion has recently made notable progress in the United States. At a trial of electric motors at Nantasket Beach, near Boston, a few days ago, it is stated that a speed exceeding sixty miles an hour was attained; and the experiment demonstrated the utility of this motor for suburban traffic. The system went into practical and regular operation on the Nantasket Beach Railway at the end of June. A successful test has also been made at Baltimore of the electric locomotive designed to draw trains through the tunnel, 7430 feet long, in that city. This and its companion—the first locomotives of the kind ever built—have each two trucks and eight wheels, sixty-two inches in diameter. Flexibly supported on each truck are two six-pole gearless motors, one for every axle. A maximum speed of fifty miles an hour is to be developed, and it is guaranteed that the locomotive will pull 1200 tons at a speed of thirty miles an hour. When coupled to a six-wheel New York Central locomotive, the electric locomotive pulled it up and down the track at will, against the pull of the steam locomotive.

AT a recent meeting of the Société Française de Physique, M. Pierre Weiss gave an account of the results of his experiments on the aelotropic magnetic properties of crystallised magnetite. The magnetisation curve of magnetite crystallised in the cubic system presents the same general features as those of iron, nickel and cobalt. The magnitude of the magnetisation (*i.e.* the permeability), however, varies with the inclination of the magnetising field to the crystallographic axes. Experiments have been made by a ballistic method suitably modified so as to permit of observations being made on very small specimens. The results thus obtained have been confirmed by other experiments in which a small disc of magnetite was rotated in a strong magnetic field, and the variations in the induction measured by means of a small coil surrounding the disc and connected to a ballistic galvanometer. The discs examined were cut parallel to the faces of the cube, octahedron and rhombic dodecahedron. If the results are expressed by drawing radii vectores from a given point of such length that they represent the magnetisation of the specimen in that direction when saturated, the surface which contains the ends of all these radii vectores is a cube with rounded edges, and with its faces slightly hollow. The magnetisation is the same in all directions contained in a plane parallel to one of the faces of the octahedron, so that the above-mentioned surface is cut by such a plane in a circular section. An experiment illustrating this aelotropic property of magnetite was shown before the Society. A small disc of magnetite placed on a plate of glass between the poles of a strong electro-magnet, turned so that one of its axes of maximum permeability was parallel to the field. Besides the difference which these experiments show between a body crystallised according to the cubic system and an isotropic body, they also show that the theories which regard magnetisation as resulting from the orientation of particles of fixed magnetic moment are insufficient to explain the magnetisation of crystalline bodies.

DURING his recent visit to the Algerian Sahara, M. Janssen made some decisive observations concerning the absorption bands near the D line of the solar spectrum, supposed to be due to atmospheric oxygen. The object was to test whether these absorption bands correspond to those observed on transmitting white light through a tube containing condensed oxygen. In some previous experiments on this question, M. Janssen had obtained these bands by means of a tube 60 m. long, containing oxygen compressed up to 6 atmospheres. An account of the Sahara observations is given in the *Comptes rendus*, together with a theoretical investigation concerning the equivalent height of the atmosphere. Starting with the remarkable law discovered by M. Janssen that the absorptive power of a gas is proportional to the thickness traversed and to the square of the density, the integration of the different layers of the atmosphere with their different densities gives 3981 m. as the equivalent thickness for a vertical ray of light. But since the density of oxygen is only 0·208 of that of the atmosphere, this number must be multiplied by 0·043, the square of that density. This gives 172 m. as the equivalent thickness of the oxygen layer. This thickness, at a pressure of one atmosphere, would not be sufficient

for showing the absorption bands, and this accounts for their absence when the sun is high in the heavens. But as the sun sets, the thickness of air traversed by its rays increases, and at an altitude of 4° the conditions are the same as those in the com. tube at 6 atmospheres pressure. At this altitude they do in fact appear, and the excessive dryness of the desert air precludes the possibility of their being due to water vapour. Thus both the terrestrial origin of these oxygen bands, and also the validity of Janssen's law of absorption, have received a striking confirmation.

THE fifth volume of the *Geographical Journal*, comprising the numbers issued during the first six months of this year, has just been published.

WE have received the Report for the year 1894-95 of the Royal Garden, Calcutta, by the Curator, Dr. G. King, issued by the authority of the Government of Bengal. It reports a considerable amount of work done in the improvement of the Gardens, and especially in the increase and arrangement of the Herbarium.

THE number of periodicals, both in Europe and America, dealing with electrical matters is considerable, the last addition to the list being the *Electrical Journal*, a new monthly published in San Francisco. The first number contains a long account of the "Express" system of telephone switchboard. Other articles appearing deal with the efficiency of electric plants, the electrical installation on board the cruiser *Olympia*, and the field of operations of an electrical engineer.

THE volume containing the *Proceedings* of the American Association for the Advancement of Science at the forty-third meeting, held at Brooklyn last August, has lately been issued. As we gave at the time a report of the work of the Sections, and printed some of the presidential addresses in full, it is only necessary for us now to say that the volume is very well produced, and contains many very valuable papers.

THE fourth and apparently concluding volume of the *Seismological Journal of Japan* has recently been published. It consists of a very valuable paper of nearly 400 pages, by Prof. Milne, "A Catalogue of 8331 Earthquakes recorded in Japan between 1885 and 1892." The materials were obtained from 968 stations, distributed over the whole empire, the total number of documents being perhaps not less than eighty or a hundred thousand. In the first catalogue are given for each shock the time of its occurrence, the land-area shaken, and data by which the position of the epicenter and the boundary of the disturbed area are approximately determined. The second catalogue states the seismic district to which each shock belongs, the lengths of the axes of the disturbed area in tens of miles, from which the total area can be roughly ascertained, and, when the shock is submarine, the distance of the epicenter from the shore. The chief object of the paper is to provide trustworthy materials for future investigations, but some results have been already obtained and are briefly described. Prof. Omori's work on after-shocks has been referred to in a previous number (vol. li. p. 423). The distribution of earthquakes in Japan forms perhaps the most important section. Earthquakes, it appears, are singularly rare in the central parts of the country, which includes the [illegible] districts where active volcanoes are numerous. The majority [illegible] originate along the eastern coast of the empire, [illegible] of submarine origin. A large number seem to [illegible] face of the steep monoclinal slope which Japan presents [illegible] the Pacific Ocean. Earthquakes are numerous where the slope is steep, and rare where it is comparatively gentle (see pp. 201-2). They are frequent in those districts where movements of secular elevation or depression are now taking place. Earthquake-sounds are often heard, but more so in the rocky mountainous districts than on alluvial plains. At the close of the paper is given a list of 301 seismic disturbances observed from 1889 to 1893 in Europe and at Teneriffe with the horizontal pendulum of Dr. von Rebeur-Paschwitz. Seven of these disturbances, and possibly five others, correspond to earthquakes in Japan.

THE flora of the Caucasus has lately been the subject of several interesting explorations and speculations by Russian botanists. The old data, contained in the works of Boissier and Ledebour, are now of little value, on account of the too broad remarks concerning the distribution of the different species, such as *Caucasus, provincia Caucasica*, and so on, which one finds in these otherwise classical works. On the other hand, such recent explorers as N. Kuznetsoff and A. Krasnoff, who have paid great attention to the composition of the floras of different parts of Caucasia, and their probable origin, have rather raised a series of most important geo-botanical questions than solved them definitively; while MM. Lipsky, Alboff, and Akinfieff have devoted their chief attention to the collection of positive systematic data, with exact indications relative to the distribution of different species. We have now in the "Memoirs (Trudy) of the Kharkoff Naturalists" (vol. xxvii.) a first instalment, by the last-named botanist, of a detailed list of plants in the middle parts of the Caucasus main ridge, with full indications concerning their vertical and horizontal distribution. Considering the generalisations of M. Kuznetsoff and M. Krasnoff as premature under our yet imperfect knowledge of the orography and geology of Caucasia, M. Akinfieff only ventures to formulate a few conclusions; namely, that the flora of Colchida is the youngest in Caucasia, as it has the least number of species, and especially of endemic forms, and that it contains but a small part of what constitutes the Mediterranean flora, as well as very little of what is found in other parts of Caucasia. The flora of Daghestan, Asiatic in its origin, has, on the contrary, in its steppe, sub-Alpine and Alpine representatives, a wide distribution over all Caucasia, with the exception of Colchida; four-fifths of the surface of Caucasia are thus genetically connected for their flora with Asia, and one-fifth only with Europe, the boundary between the two being, not the main ridge, but a broken line running approximately from Stavropol, or rather north of this town, along the water-parting between the Kuban and the Terek, to the Elborus, along the main ridge to the Adai-khokh, and further to the Mesques Mountains and the Suram Pass. It should be said that this conclusion seems to agree very well with what we now learn about the orgraphical structure of Caucasia, from which it appears more and more that the Mesques Mountains must be considered as a continuation of the border-ridge of the Asia Minor plateau, which ridge runs along the south-eastern coast of the Black Sea, and is continued north-east to meet the main ridge.

WE have received from Dr. Doberck, Government Astronomer of Hong Kong, the report of that observatory for 1894, containing *inter alia* an account of nineteen typhoons which occurred during the year, and the paths of which have been laid down on two plates. Information regarding storms is regularly exhibited and telegraphed whenever they can be justified by the observations received, but the work is apparently much interfered with by the tardy arrival of telegrams from the outlying stations. For the purpose of elucidating the behaviour of typhoons and other meteorological features, observations are regularly extracted from the logs of ships which visit the China seas, and tabulated for future use; in addition to these, observations are received from about forty land stations. The astronomical and magnetical work of the observatory has been regularly carried on, as in former years.

WHEREAS a few years ago the discovery of a new spirillum form was hailed as a bacteriological novelty, we are now constantly receiving fresh additions to this interesting group of microbes. With improved methods their detection and isolation have been rendered comparatively easy, and they are now found fairly widely distributed in water. Sanarelli isolated no less than thirty-two different vibrios from the river Seine, sewage-effluent, and pond water, and various authorities in Germany have detected such forms in rivers. So far the larger number have been obtained from river water, and have been but rarely met with in well water; but quite recently MM. A. Zawadzki and G. Brunner, of the Imperial Institute for Preventive Medicine in St. Petersburg, have discovered and isolated three vibrios from polluted well water, which do not liquefy gelatine, and in other respects are easily distinguishable from Koch's cholera vibrio. As regards their pathogenic properties, it is stated that white mice were quite unaffected when the vibrios were subcutaneously introduced. The investigations and descriptions have been carefully done and are fully recorded, and the authors are persuaded that they have discovered new forms. It is, however, difficult to decide this point, for only a slight acquaintance with the literature of the subject is apparent; and whilst the authors complain that Eisenberg's catalogue of bacteria is out of date, and those of Roux and Lustig are respectively incomplete, they do not appear to have any acquaintance with Percy Frankland's "Micro-organisms in Water," containing descriptions of over 200 bacteria found in water, neither have they consulted many important memoirs on vibrios which have been published in recent German and French journals.

THE writer of the note on p. 277, referring to hygrometric observations on the Sonnblick mountain, inadvertently wrote, "atmospheric electricity," instead of "atmospheric humidity," in the second line of the note.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Mrs. A. Canning Fysh; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. A. Kagele; an Irish Stoat (*Putorius hibernicus*) from Ireland, presented by the Viscount Powerscourt; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Miss Dorothy Lowndes; a Bosch-bok (*Tragelaphus sylvaticus*) from South Africa, presented by Mr. W. Champion; six Orbicular Horned Lizards (*Phrynosoma orbiculare*) from Mexico, presented by Mr. E. J. Scarbrough; a West African Python (*Python sebæ*) from West Africa, presented by Mr. Edward Straw; a Red-sided Tit (*Parus varius*) from Japan, a White-browed Amazon (*Chrysotis albifrons*) from Honduras, two Adorned Terrapins (*Clemmys ornata*) from Central America, deposited; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ALTITUDE AND AZIMUTH OF POLARIS.—It is a matter of common knowledge that the Pole star is about a degree and a quarter from the true pole, so that azimuths and latitudes cannot be directly determined by observations of this star. The usual mode of procedure is to employ tables reducing the observations to the true pole; a graphical method of performing this rather tedious reduction, with an accuracy sufficient for most purposes, has been devised by A. Tanakadate, of Tokio (Sūgakub.-Kizi.) It is shown that the usual formula for the calculation of azimuth corresponds very nearly with the equation of a circle of radius $p \sec \phi$ (p being the polar distance of Polaris, and ϕ the latitude of the place of observation), and the centre of which is displaced above the origin by an amount equal to $\frac{p^2 \tan \phi}{\cos \phi}$. An origin being chosen near the middle of a sheet of squared paper, degrees and minutes are marked off along the axes in both directions, and a circle is drawn on the same scale with radius and displacement of centre adapted to the latitude as defined above. Radiating straight lines drawn from the origin correspond to different hour angles, the line $t=0$ being that along which the centre of the circle is displaced. The abscissa of the point where the line corresponding to the hour angle at which an observation is made cuts the circle, gives directly the azimuth of Polaris, the star being east or west of the true north according as the point lies to the right or left of the origin in the diagram. Neglecting errors of construction, the readings will only differ by a few seconds from the calculated results, and it is shown that even these errors can be reduced by slightly enlarging the radius of the circle.

If a circle be drawn from the origin as centre, with radius equal p, the diagram can also be used for reducing the latitude from observations of the Pole star by giving a small correction to the hour angle, $\frac{1}{2} p \tan h \sin t$, where h is the observed altitude, and t the hour angle. The ordinate of this circle gives the correction to be applied to the observed altitude in order to obtain latitude.

It is pointed out in the paper that these principles may easily be embodied in an instrument, and, in fact, such a contrivance is now in use among the students of astronomy in the Imperial University.

OBSERVATIONS OF DOUBLE STARS.—The measurements of position angles and distances of double stars made at the Paris Observatory from July 1890 to the end of last year, are published by M. Bigourdan in a very concise form in the *Bulletin Astronomique* for July. The telescope employed was that of the western tower, having an object glass 0·305 m. diameter and a focal length of 5·25 m., the magnifying power usually being 478. Most of the observations were made in the twilight or in the early night, at which times the star images are at their best. The list of stars observed includes about 150 from the Dorpat catalogue, 76 from the Pulkowa catalogue, and nearly 30 others; in many cases there are long series of measures of the same pair. A filar micrometer was employed.

At the Berlin Observatory, Dr. V. Knorre has used a double image micrometer in the measurement of double stars, and some of the results are given in *Ast. Nach*, 3300. The measures appear to agree very well with those of M. Bigourdan, in the case of stars common to the two sets of observations.

A GREAT NEBULA IN SCORPIO.—In the course of his work on the photography of the Milky Way, Prof. Barnard exposed a plate on the region near Antares for 2h. 20m. on March 25, 1895. The resulting negative showed a vast and magnificent nebula, intricate in form, and apparently connected with many of the bright stars of that region, including Antares and σ Scorpii. The nebula is gathered in cloud-like forms, the greatest masses being around ρ Ophiuchi and two neighbouring small stars. This photograph was taken with the Willard lens of 6 inches aperture, with which Prof. Barnard has previously obtained such splendid results.

Even more interesting is a photograph of the same region taken with a "lantern lens" of $1\frac{1}{2}$ inches aperture and 5 inches equivalent focus, the exposure being 2h. 18m. The scale of this photograph is about 10° to the inch, and in addition to bringing out some new points about the great nebula, it shows the sky itself in that region to be very wonderful. The first photograph had shown that the nebula occupied a singularly blank part of the sky, from which large vacant channels diverged towards the east, and the negative taken with the lantern lens showed that these channels ran irregularly eastward for 15° or 20°.

The photograph taken with the lantern lens shows that the new nebula extends southward for two or three degrees beyond Antares and σ Scorpii in a southward direction. An elongated nebula about 2° or 3° long, involving the star ν^2 Scorpii, is also seen on the photograph.

Prof. Barnard goes on to say that "this magnificent nebula is one of the finest in the sky, and as it involves so many of the bright stars in that region it would imply that they are essentially at the same distance from us." (*Ast. Nach.* 3301). The unpretentious character of one of the instruments employed by Prof. Barnard is not the least remarkable feature about this new discovery.

New Variable Stars.—*Wolsingham Observatory Circular*, No. 42, received from the Rev. T. E. Espin, announces that a red star of Secchi's Type III., magnitude 8·4, was detected at his Observatory on July 14, in R.A. 10h. 52·4m., Decl. 2° 11′ (1900). The star is probably a new variable, and is not in the southern *Durchmusterung*. The star designated Espin 1021 is also probably variable.

THE BRITISH MEDICAL ASSOCIATION.

As already noted, the sixty-third annual meeting of the British Medical Association will be held in London next week. From the programme of final arrangements published in the current number of the *British Medical Journal*, it is evident that the meeting will be of exceptional interest and importance. The President-elect is Sir J. Russell Reynolds, Bart. An address in Medicine will be delivered by Sir William Broadbent, Bart.; an address in Surgery by Jonathan Hutchinson, F.R.S.; and an address in Physiology by Prof. Edward Albert Schafer, F.R.S. The scientific business of the meeting will be conducted in fifteen sections: Numerous papers have been received by each Section, and specific points have been selected for discussion. In the Section of Medicine, presided over by Dr. F. W. Pavy, F.R.S., the following subjects have been selected for discussion: (1) Diphtheria and its treatment by the antitoxin; acute lobar or croupous pneumonia, its etiology, pathology, and treatment; the causes of acute rheumatism and its relation to other affections. The President of the Surgery Section is Sir William MacCormac, who will make some introductory remarks, in which he will refer to the effects produced by modern rifle bullets on the human body. The following subjects have been selected for discussion: The diagnosis and treatment of fractures of the upper third of the femur, including the neck; the surgical treatment of cysts, tumours, and carcinoma of the thyroid gland and accessory thyroids. Sir William Priestley presides over the Section of Obstetrics and Gynæcology. The President of the Section of Public Medicine is Dr. Ernest Hart. The regular business of this Section will commence each day with a formal discussion by gentlemen who have been invited to open the debates. The subjects selected are as follows: Presidential address: Water-borne disease and its prevention; discussions upon the regulation of the slaughter of animals for human food and the inspection of animals before and during slaughter; the insecurity of tenure of extra-Metropolitan Medical Officers of Health under the Public Health Act, 1875. The Section of Psychology has for its President Dr. W. J. Mickle. The President will open the section with an address on the brain. A discussion has been arranged to take place on each day, the subjects being: On the treatment of melancholia; on insanity, in relation to criminal responsibility; on epilepsy, and its relation to insanity. The President of the Physiology Section is Dr. David Ferrier, F.R.S. In this Section a discussion on the mechanics of the cardiac cycle will be introduced by Prof. Haycraft and Dr. D. Paterson; the following will take part: Dr. Noel Paton, Dr. Lauder Brunton, F.R.S., and Dr. Gibson. The Anatomy and Histology Section has for its President Mr. Henry Morris. The following subjects have been selected for discussion: Art in its relation to anatomy; the development and structure of the placenta; the topographical anatomy of the abdomen. The President of the Section of Pathology and Bacteriology is Dr. Samuel Wilks, F.R.S. The work of the Section includes the demonstration of the malaria parasite by Dr. P. Manson, with some facts as to its life-history. There will be a discussion upon this, and upon neuritis; vaccinia and variola; pernicious anæmia; and lymphadenoma. The President of the Section of Ophthalmology is Mr. H. Power. The following discussions have been arranged in this Section: On [illegible] of recurrent ophthalmia; on the diagnosis of [illegible]; on the question of operating in chronic glaucoma. The Section of Diseases of Children has for its President Mr. John H. Morgan; and the President of the Section of Otology is Sir W. Dalby. The Section of Pharmacology and Therapeutics has for its President Sir William Roberts, F.R.S. In this Section there will be a discussion upon serum therapeutics, and [illegible] requirements of the profession with reference to the revision of the *British Pharmacopœia*. Dr. Felix Semon is the President of the Section of Laryngology; and Dr. H. Radcliffe Crocker, of the Dermatology Section. Finally, the ethics of the medical profession has a Section to itself, presided over by Dr. W. F. Cleveland. Only members of the British Medical Association, invited guests, and accredited strangers, will be allowed to attend the general meetings or the meetings of Sections. The reception-rooms will be opened on Monday, July 29, at 12 o'clock noon. The members' reception-room is in the large hall of King's College. A separate reception-room has been provided for invited foreign guests next to the members' reception-room, and another for ladies at the Royal Society's Rooms, Burlington House. The arrangements for the conduct of the work of the Sections, and for the comfort of the members, have been admirably arranged, so there is every promise that the meeting will be a very successful one.

HELIUM, A CONSTITUENT OF CERTAIN MINERALS.[1]

I.

The gas obtained from the mineral cleveite, of which a preliminary account has been communicated to the Royal Society (*Proceedings*, May 2, 1895), has been the subject of our investigation since the middle of April. Although much still remains to be done, enough information has been gained to make us believe that an account of our experiments, so far as they have gone, will be received with interest.

We have attempted to ascertain, in the first place, from what minerals this gas, showing a yellow line almost, if not quite, identical in wave-length with the line D_3 of the chromospheric spectrum, and to which one of us has provisionally given the name "helium"—a name applied by Profs. Lockyer and Frankland some thirty years ago to a hypothetical solar element, characterised by the yellow line D_3 of wave-length 5875·982 (Rowland). We may state at once that it is not our purpose to attempt to prove this coincidence, but willingly to leave the subject to those who are more practised in such measurements.

We propose therefore, first, to discuss the terrestial sources of this gas; second, to describe experiments on products from several sources; and last, to propound some general views on the nature of this curious substance.

1. *The Sources of Helium.*

It is usual in a memoir of this kind to cite previous work on the subject. It would be foreign to our purpose to discuss observations on the solar spectrum; our memoir deals with terrestrial helium. And we have been able to find only one short note of a few lines on the subject; it is a statement by Signor Palmieri (*Rend. Acc. di Napoli*, xx. 233), that on examining a lava-like product ejected by Vesuvius, he found a soft substance which gave a yellow spectral line of wave-length 587·5; he promised further researches, but, so far as we know, he did not fulfil his promise. He does not give any details as to how he examined the mineral.

An account has already been given in Part I. of Dr. Hillebrand's investigations on the gases occluded by various uraninites which he was so unfortunate as to mistake for nitrogen. Dr. Hillebrand was so kind as to supply us with a fair quantity of the uraninite he employed; and it is satisfactory to be able to confirm his results so far; for it is beyond doubt that the gas evolved from his uraninite by heating it in a vacuum or by boiling with sulphuric acid contains about 10 per cent. of its volume of nitrogen. It is therefore not to be wondered at, that he formed the conclusion that the gas he had was nitrogen; for he obtained some evidence of the formation of nitrous fumes on passing sparks through a mixture of this gas with oxygen; he succeeded in obtaining a weighable amount of ammonium platinichloride from the product of sparking it with hydrogen in presence of hydrochloric acid; and, in addition, he observed a strong nitrogen spectrum in a sample of the gas transferred to a vacuum tube. Had he operated with cleveite, as will be shown later, he would have in all probability discovered helium (*Bull. U.S. Geological Survey*, lxxviii. 43).

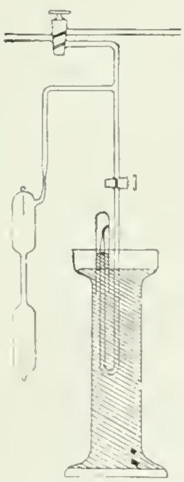
To extract the gas from small quantities of minerals, from 2 to 5 grams of the coarsely powdered substance was heated in a small bulb of combustion-tubing, previously exhausted by a Töpler's pump. As it was found that water and carbon dioxide were often evolved, a soda-lime tube and a tube filled with phosphoric anhydride were often interposed between the bulb

[1] A paper by Prof. William Ramsay, F.R.S., Dr. J. Norman Collie, and Mr. Morris Travers, read before the Chemical Society on June 20.

and the pump. After most of the gas had been evolved, the temperature was raised until the hard-glass bulb began to collapse.

Many of the minerals evolved hydrogen; hence, after the gas had entered the pump, the bulb was completely exhausted, and the gas was sparked with oxygen, no alkali being present. The oxygen was then absorbed with caustic soda and pyrogallic acid, and the gas was transferred to a vacuum-tube. As this process of transference proved very convenient, it is worth while to describe it in full.

The apparatus is shown in the annexed figure. It consists of a tube provided with a perfectly-fitting stop-cock; this tube is connected with a Töppler's pump. The vacuum-tube or tubes to be fitted are sealed to a lateral branch above the stop-cock. The lower part is bent into a sharp U, and the end drawn out to a point and sealed. The stop-cock is then turned full on, and the whole tube is completely exhausted, until the vacuum-tube shows brilliant phosphorescence, or, indeed, as often happens, ceases to conduct the discharge; the stop-cock is then closed. A mercury trough is placed below the bend of the tube, and the latter is sunk until the closed end disappears below the mercury. A small tube, which need not contain more than 1 c.c. of the gas to be introduced into the vacuum-tube, is then placed over the closed end of the bent tube, and the mercury trough is lowered. The sealed end is then broken by pressing it against the interior of the gas-tube, when gas enters up to the stop-cock. On carefully opening the stop-cock a trace of gas is passed into the vacuum-tube; this gas is then



pumped out and collected below the delivery tube of the Töppler's pump. One such washing with gas is usually sufficient. The stop-cock is again opened, and a sufficient amount of gas introduced into the vacuum-tube to show the spectrum. The vacuum-tube is then removed by sealing, and the gas still remaining in the bent tube may be transferred to the pump and collected. It is seen that this method permits of the filling of a vacuum-tube absolutely without loss, and it may be added with great expedition.

The results obtained with the minerals examined are given in the following table.

The spectrum of helium is characterised by five very brilliant lines; these occur in the red, the yellow, the blue-green, the blue, and the violet. In every case, except with hjelmite, fergusonite, and xenotime, in which cases the lines were merely seen, all these lines were identified by simultaneous comparison in the same spectroscope with the spectrum of helium from clèveite. With the gas from samarskite and in some other cases a still more careful comparison was made, and the absolute coincidence of every visible line was ascertained.

From many of these minerals, a hydrocarbon was extracted; this was manifested by the non-absorption of the gas by caustic potash until after explosion with oxygen. It would be interesting to ascertain whether the hydrocarbon is present as such in the mineral, or is formed during the heating, for in all cases where a hydrocarbon was evolved, a large quantity of hydrogen was also obtained. If a vacuum-tube be charged with the crude gas, merely deprived of carbon dioxide by caustic alkali, the spectrum consists almost wholly of the fluted bands of carbon.

Name of mineral.	Source.	Result.
Yttrotantalite ...	Rachwane, Ceylon	Hydrogen and helium.
Samarskite	Unknown	A little hydrogen and nitrogen. After sparking with oxygen over caustic soda, 15 grams yielded approximately 4 c.c. of helium. At high pressure (4 mm.) the unsparked gas shows fluted carbon spectrum. At low pressures this is invisible.
Hjelmite	Fahlun, Sweden...	No hydrogen: trace of helium.
Fergusonite ...	Ytterby, Sweden..	Do. do.
Tantalite	Fahlun, Sweden...	Trace of helium.
Pitchblende ...	Cornwall	50 grams yielded about 0·5 c.c. of helium. After fusion with hydrogen potassium sulphate a further very small quantity was obtained.
Pitchblende ...	Unknown	Small quantity of helium.
Polycrase	Hitterö, Norway..	Do. do.
All these minerals contain uranium.		
Monazite... ...	N. Carolina	Contains hydrogen and helium in fair quantity.
,, ...	Fahlun, Sweden...	Do. do.
,, ...	Bahia	Do. do.
,, ...	Skrotorp, near Moss, Norway...	Do. do.
Xenotime	Brazil	Hydrogen, and, after explosion with oxygen, a trace of helium.
Orangeite	Near Arendal......	Easily gave a good spectrum of pure helium.
Columbite	N. America	Much hydrogen: no helium.
Perofskite ...	Magnet Cove, Arkansas	Very little gas; partly hydrogen.
Wazite...........	Sweden	Hardly any gas: trace of hydrogen.
Thorite	Norway	Fair quantity of hydrogen.
Fluocerite	Unknown	Carbon dioxide; glass etched.
Orthite	Hitterö, Norway..	Carbon dioxide and small quantity of hydrogen.
Gadolinite	,, ,,	Carbon dioxide and small quantity of hydrogen.
Euxenite	,, ,,	Do. do.
Cerite	Unknown	90 grams gave 50 c.c. of gas, leaving 1·3 c.c. after explosion with oxygen. After sparking and absorbing oxygen, 0·1 c.c. remained. Not examined.
Blende ..	Unknown	No gas.
Rutile	,,	,,
Gummite.. ...	Flat Rock Mine, Mitchell Co., N. Carolina	No gas, except a trace of carbon dioxide.
Pyrolusite .	Unknown	Only oxygen.
Native platinum	Brazil	Trace of oxygen.
,, ,,	Siberia	Trace of oxygen in larger quantity, and trace of nitrogen.

It is here of interest to inquire which constituent of these minerals is effective in retaining helium. For this purpose, it is necessary to know their composition: but it has not been possible to make accurate analyses of all the samples of minerals treated. Hillebrand supposed that the gas was retained by the uranium, and states that its volume varies roughly with the amount of uranium oxides present. To decide the question, it is necessary to consider the composition of these minerals in some detail.

Yttrotantalite is essentially a tantalate of yttrium and calcium, containing a little tungstic acid, and small amounts of iron and uranium. The yield of helium was here small.

Samarskite is a niobate of uranium, iron, and yttria, containing smaller amounts of tungsten, zirconium, and thorium. The amount of uranium oxide is about 11 or 12 per cent.; of thorium oxide about 6, of yttrium 13, and of cerium 3. It yields a moderate amount of helium.

Hielmite closely resembles tantalite in composition, but contains stannic oxide. The yield of helium was minute.

Fergusonite is a niobate of yttrium and cerium, containing only a small amount of uranium, zirconium, tin, tungsten, &c. The yield of helium was here minute.

Tantalite consists of tantalate of iron and manganese; the helium obtained was a mere trace.

Pitchblende consists mainly of the oxide, U_3O_8. The rare metals are present in English pitchblende in very minute amount. The helium obtained was very minute in quantity, and had a large amount of the mineral not been used it would doubtless have escaped detection.

Polycrase is a niobate of uranium, containing titanium, iron, yttrium, and cerium. The amount of helium obtained from it was small.

These minerals, it will be seen, all contain uranium. To them must be added cleveite and broggerite, from which by far the best yield was obtained.

Monazite, which gave a good yield of helium, is a phosphate of cerium, lanthanum, and thorium, but does not contain uranium. It might serve, if necessary, as a source of helium, for it is comparatively cheap; it would form a more economical source than either cleveite or broggerite.

Xenotime is a phosphate of yttrium, and yields a trace of helium.

Orangite and *Thorite* are silicates of thorium containing small quantities of uranium and lead. The former of these yielded a fair amount of helium, but none could be obtained from a larger quantity of the latter.

From these details, it may be concluded that the helium is retained by minerals consisting of salts of uranium, yttrium, and thorium. Whether its presence is conditioned by the uranium, the yttrium, or the thorium, we are hardly yet in a position to decide. To judge by the Cornish ore, oxide of uranium alone is sufficient to retain it; but that its presence is not absolutely necessary is shown by its existence in monazite and xenotime. The high atomic weights of uranium and thorium, and the low atomic weight of helium suggest some connection; and yet yttrium, which possesses a medium atomic weight, sometimes appears to favour the presence of the gas; for yttrium is present in yttrotantalite, which, however, contains uranium, and in cleveite, in which uranium is present in relatively large amount.

None of the oxides of uranium, when heated in helium and allowed to cool, retains the gas; but similar experiments have not yet been made with oxides of thorium and yttrium, or with mixtures of these with uranium oxide.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

M. Liard, Director of higher education in France, has been raised to the rank of Commander in the Legion of Honour.

By the will of the late Mrs. Fraser, widow of the late Bishop of Manchester, a sum of £3000 is bequeathed to Oriel College, Oxford, for the foundation of a Scholarship.

Mr. Henry [illegible], who was an evening student in the Chemical Department of the Finsbury Technical College, has been elected by the Technical Instruction Committee of Accrington Town Council to the post of Principal and Head Master of the Accrington Municipal Technical Schools, just erected at a cost of £12,000.

After ten years of quiet and unostentatious work in temporary buildings, the authorities of the Cambridge Training College for Women Teachers have been able to erect large and handsome college buildings by means of a grant from the Pfeiffer Bequest and voluntary subscriptions. The new buildings will be formally opened on Saturday, October 19, by the Marquess of Ripon, and other well-known persons interested in education have promised to take part in the proceedings. Practical demonstrations will be arranged to illustrate some of the latest developments of educational method, both in teaching and training, so as to make the occasion one of special interest to those who are taking a share in the development of secondary education in England. The experiment of training teachers under new conditions, and to some extent on new lines, under the shadow of an old University, is of special interest, and the opening ceremony will afford a unique opportunity to those interested in secondary education to learn something of the nature and results of this experiment.

Her Majesty's Commissioners for the Exhibition of 1851 have made the following appointments to science research scholarships for the year 1895, on the recommendation of the authorities of the respective universities and colleges. The scholarships are of the value of £150 a year, and are tenable for two years (subject to a satisfactory report at the end of the first year) in any university at home or abroad, or in some other institution approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country: University of Edinburgh, John D. F. Gilchrist; University of Glasgow, Walter Stewart; University of St. Andrews, Henry C. Williamson; University College, Dundee, James Henderson; Mason College, Birmingham, Robert H. Pickard; University College, Bristol, Samuel R. Milner; University College, Liverpool, John T. Farmer; University College, London, Emily Aston; Owens College, Manchester, William H. Moorby; Durham College of Science, Newcastle-on-Tyne, Alexander L. Mellanby; University College, Nottingham, Martin E. Feilmann; Queen's College, Belfast, William Hanna; M'Gill University, Montreal, Robert O. King; Queen's University, Kingston, Canada, Thomas L. Walker; University of Sydney, John A. Watt; University of New Zealand, Ernest Rutherford.

SCIENTIFIC SERIALS.

American Meteorological Journal, June. The principal articles are:—The Thermophone, by H. E. Warren and G. C. Whipple. This is an instrument for measuring temperature, particularly of distant or inaccessible places. It was devised by the authors for the purpose of obtaining the temperature of the water at the bottom of a pond, but is also suitable for obtaining the temperature of the soil at various depths. The apparatus resembles Siemen's resistance thermometer, advantage being taken of the fact that different metals have different electrical temperature coefficients. The instrument is not yet self-recording. California electrical storms, by J. D. Parker. The object of the paper is to inquire into the causes of the infrequency of electrical storms in California. At San Diego, for instance, the Weather Bureau has only reported two electrical storms in the last sixteen years. Among the principal causes, the author mentions the humidity of the atmosphere, the absence of excessive heat during the rainy season (September to May), and the absence of cyclones during the dry season (May to September).

Wiedemann's Annalen der Physik und Chemie, No. 6. Survey of the present position of energetics, by Georg Helm. The two directions in which the conversion of physics into a science of energy has been most successfully carried out are those of mechanics and of thermodynamics. Two views of energy are at present struggling for supremacy, that which regards energy as a mathematical abstraction, non-existent except in equations, and that which regards energy as a concrete reality, filling space, and migrating continuously from one place to another. One of the chief generalisations of the science of energetics is this: In order that something may happen it is

sufficient and necessary that uncompensated differences of intensity exist.—Influence of gases in solution upon the silver voltameter, by John E. Myers. (See p. 276). –The aureole and stratification in the electric arc, and in discharges in rarefied gases, by O. Lehmann. The appearance of the electric arc with horizontal carbons is that of two gas jets burning against each other, and flaring vertically upwards. This is due to the currents of hot air ascending between them, and is the same as if the carbons were joined by a white-hot wire. There is no fundamental difference between the arc and discharges in rarefied gases, as may be shown by taking very small terminals or very large discharge vessels for the latter. That the current travels not only through the arc proper, but also through the surrounding "aureole," may be proved by approaching a magnet, which bends the aureole aside.—Magnetism of asbestos, by L. Bleekrode. The grey variety of asbestos is highly magnetic. Strips of so-called asbestos paper 4 by 3 cm. are attracted at 1 cm. distance by an electromagnet capable of carrying 5 kgr., and fibres of pure asbestos attract small particles of the same substance. Asbestos should only be used with great care in sensitive magnetic instruments.

Bulletin de l'Académie Royale de Belgique, No. 4.—On the specific heat of peroxide of hydrogen, by W. Spring. The method of cooling was employed, and aqueous solutions of various strengths were experimented upon. A 74 per cent. solution gave the value 0·6893, which fell to 0·6739 at 71 per cent., 0·6276 at 60 per cent., and 0·6208 at 34 per cent. On further dilution to 31 per cent. the specific heat rose again to 0·8065. Peroxide of hydrogen thus behaves very much like a solution of alcohol. Chemical decomposition probably exerts a strong influence upon the values at high concentrations, and 0·6208 must be taken as a superior limit. Woestyn's law would give 0·6840. Hence it follows that the internal work of hydrogen peroxide must be less than that of water. On metageometry and its three subdivisions, by P. Mansion. The author gives a sketch of a system of geometry of n dimensions, by which the three varieties, those due to Euclid, Riemann, and Lobatchevski, respectively, can be deduced from elementary considerations. The theorem that a straight line, two of whose points lie in a plane, lies in that plane altogether, applies to all the varieties. But Riemann's geometry is characterised by the proposition: If, in a plane, two straight lines which intersect in a point A also intersect in a second point B, all straight lines passing through A will also cut the line A B a second time. If the sum of the three angles of a single triangle is equal to two right angles, the same applies to all triangles, and the space will be Euclidean. In Riemann's curved space this sum is greater, and in Lobatchevski's curved space it is less than two right angles.—On the period of frost extending from January 27 to February 17, 1895, by A. Lancaster. This amount of frost is unprecedented since 1838, when the mean of the minima for the days between January 8 and 27 was $-13^{\circ}\cdot 4$ C. at Brussels. This year the mean was -11° C. The isothermals of mean temperatures during this period for Belgium show maxima of frost on the frontier of Limburg and north of Hasselt, the least cold being along an isothermal of -5° passing along the coast through Ostende.—On a silicate which probably constitutes a new mineral species, by G. Cesaro. This mineral, which accompanies hexagonite (a violet manganiferous tremolite), comes from St. Lawrence County, N.Y. It is colourless, or a delicate opaline-pink. Its hardness is 45. It crystallises in the orthorhombic system, and presents two cleavages along two planes of symmetry. Hitherto it has probably been taken for enstatite, but it is distinguished from this by the sign of its bisectrix, by the absence of well-defined prismatic cleavages, by its fusibility before the blowpipe, and by its angles. From anthophyllite it is distinguished by the absence of iron.—Lunar topographical measurements taken on photographs, compared with the records of Lohrman and Madler, by W. Prinz. A table is given of twelve craters near the centre of the disc, with the values of their diameters from the maps and photographs. The greatest difference between the two cartographers appears in the case of Ptolemæus, whose crater is given 21,518 m. broader by Madler than by Lohrmann, and the latter observer is confirmed by the photographs.

Bulletin de l'Académie Royale de Belgique, No. 5.—Chlorobromomalic anhydride, by Dr. A. J. J. Vandevelde. This is obtained by the action of bromine upon chlorofumaryl chloride. It is easily sublimed, even at ordinary temperatures, in a current of dry air, and can be purified in this manner. Its formula appears to be $CCl.CBr.(CO)_2O$. It fuses at 113° and boils at 203°. It has a very irritating but not disagreeable odour, and violently attacks the mucous membranes. It is soluble in alcohol, ether, chloroform, carbon bisulphide, and benzol, and easily crystallises in needles by concentration. When sublimed, it crystallises in plates. Water only dissolves it slowly, and an aqueous solution, when spontaneously evaporated, gives a very soluble deliquescent substance, which only crystallises when nearly dry.

Proceedings of the St. Petersburg Society of Naturalists, vol. i. No. 1–3.—The St. Petersburg Society of Naturalists has introduced this year a most welcome improvement in its publications. The *Proceedings* of the Society are now published separately, in advance of the *Memoirs*, and all the communications are summed up by the authors themselves in French or in German. We have already received three fascicules of the *Proceedings*, which contain a number of interesting communications: on the petrography of central Caucasus and on Vesuvian lavas, by M. Loewinson-Lessing; on the morphology and phylogenetic relations of the Myriapoda, by P. Schmidt, from which we learn that the *Pauropus Huxleyi* is possessed of a pair of tracheas, of a very plain structure, which open under the mandibles: on the flora of the Zerafshan region in Turkestan, by W. Komaroff; on the embryology of the Diplopodes, by N. Cholodkovsky; on the lymph glands of the earthworms, by G. Schneider; on geological researches in the Altai, by Prof. Inostrantseff; on the formation of the egg in the *Dytiscus*, by K. Saint-Hilaire; and on the Pantopodes of the Arctic Ocean and the White Sea, being a review of the species described and collected both by the author and different previous explorers, with a description of one new species and two new varieties.

Memoirs (Trudy) of the St. Petersburg Society of Naturalists, vol. xxiv., Section of Botany.—Besides the *Proceedings*, this volume contains two important works:—The sub-genus *Eugentiana* of Tournefort's genus *Gentiana*, by N. Kuznetsov, being an elaborate work of 530 pages, with a plate and geographical maps, and containing the systematic description of this sub-genus, established by the author, its morphology, and the geographical distribution of its species.—The flora of Crimea, by W. Agéenko, part ii., first fascicule, containing the tribes from the Ranunculaceæ to the Capparideæ. In the first volume of this work the author gave a review of the literature of the subject, as well as a review of the collections of Crimean plants which he had at his disposal, and an excellent sketch of the flora of Crimea and its dependency from the local physical and geological features of the country. Now he gives the full list of the vascular plants of Crimea, which will be followed by a review of the geological changes undergone by Crimea and their influence upon the present composition of the flora.

Bollettino della Società Sismologica Italiana, vol. i., 1895, Nos. 1, 2.—Whether, and to what extent, an earthquake-wave can afford criteria for reasoning with regard to the nature of the formations traversed by it, by Prof. P. M. Garibaldi.—On conical or horizontal pendulums, by Prof. G. Grablovitz. In this paper is described a simple form of horizontal pendulum designed for timing, or calling attention to, the beginning of a disturbance. The mode of suspension resembles that adopted by Gerard and Milne, and from the mass at the free end of the horizontal rod there projects downwards a wire into a small cup of mercury. When the pendulum is disturbed, an electric circuit is closed, and a bell is rung, or the time determined by stopping a clock, &c. The Lecco earthquake of March 5, 1894, by Dr. M. Baratta. This earthquake was a very slight one, and its interest lies in the discovery by its means of a new centre of disturbance in Lombardy, with which other slight shocks may also be connected. The relation between these earthquakes and the geological structure of the district is discussed.—Vesuvian notes (1892–93), by Prof. G. Mercalli.—Seismoscope for electrical registration, by Prof. G. Mugna.—Geodynamic levels for continuous registration, by Prof. G. Grablovitz. The author has had two water-levels constructed for the geodynamic observatory at Ischia. They are each $2\frac{1}{2}$ metres long, and are arranged north-south and east-west. The movements of the ground are indicated by floats, whose displacements are magnified fifty times by levers carrying pens at their free ends. Copies of the record obtained from the Laibach earthquake of April 14 are given.—On the velocity of propagation and on the length of seismic waves, by Prof. F.

Omori. (See p. 275.)—Notes on the state of Etna, by Prof. A. Riccò.—Notes on Italian earthquakes (January, February, 1895), by Dr. M. Baratta. These are inserted as an appendix to each number, and form a catalogue of all earthquakes, tremors and pulsations recorded at the Italian geodynamic and meteorological observatories, &c. They are a continuation of the valuable *Supplementi* to the *Annali* of the Ufficio Centrale di Meteorologia e Geodinamica.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 20.—"A Dynamical Theory of the Electric and Luminiferous Medium. Part II.: Theory of Electrons." By Joseph Larmor, F.R.S.

In a previous paper on this subject,[1] it has been shown that by means of a rotationally elastic æther, which otherwise behaves as a perfect fluid, a concrete realisation of MacCullagh's optical theory can be obtained, and that the same medium affords a complete representation of electromotive phenomena in the theory of electricity. The ponderomotive electric forcives were, on the other hand, deduced from the principle of energy, as the work of the surplus energy in the field, the motions of the bodies in the field being thus supposed slow compared with radiation. It was seen that in order to obtain the correct sign for the electrodynamic forcives between current systems, we are precluded from taking a current to be simply a vortex ring in the fluid æther; but that this difficulty is removed by taking a current to be produced by the convection of electrons or elementary electric charges through the free æther, thus making the current effectively a vortex of a type whose strength can be altered by induction from neighbouring currents. An electron occurs naturally in the theory as a centre or nucleus of rotational strain, which can have a permanent existence in the rotationally elastic æther, in the same sense as a vortex ring can have a permanent existence in the ordinary perfect fluid of theoretical hydrodynamics.

In the present paper a further development of the theory of electrons is made. As a preliminary, the consequences as regards ponderomotive forces, of treating an element of current $\iota\delta s$ as a separate dynamical entity, which were indicated in the previous paper, are here more fully considered. It is maintained that a hypothesis of this kind would lead to an internal stress in a conductor carrying a current, in addition to the forcive of Ampère which acts on each element of the conductor at right angles to its length. Though this stress is self-equilibrating as regards the conductor as a whole, yet when the conductor is a liquid, such as mercury, it will involve a change of fluid pressure which ought to be of the same order of magnitude as the amperean forcive, and therefore capable of detection whenever the latter is easily observed. Experiments made by Profs. FitzGerald and Lodge on this subject have yielded purely negative results, so that there is ground for the conclusion that the ordinary current-element $\iota\delta s$ cannot be legitimately employed in framing a dynamical theory.

This result is entirely confirmed when we work out the properties of the field of currents, considered as produced by the convection of electrons. It is shown that an intrinsic singularity in the æther, of the form of an electron e, moving with velocity $(\dot{x}, \dot{y}, \dot{z})$ relative to the quiescent mass of æther, is subject to a force e (P, Q, R), given by equations of the form

$$P = c\dot{z} - b\dot{y} - dF/dt - d\Psi/dx;$$

in which (a, b, c) is the velocity of flow of the æther where the electron is situated, and is equal to the curl of (F, G, H) in such way that the latter is Maxwell's vector potential given by the formula of the type

$$F = \int \frac{u}{r} d\tau + \int \left(B\frac{d}{dz} - C\frac{d}{dy} \right) \frac{1}{r} d\tau;$$

and where Ψ is the electrostatic potential due to the electrons in the field, so that $\Psi = c^2 \Sigma e/r$, where c is the velocity of radiation. These equations are proved to hold good, not merely if the motions of the electrons are slow compared with radiation, as in the previous paper, but quite irrespective of how nearly they approach that limiting value; thus the phenomena of radiation itself are included in the analysis.

An element of volume of an unelectrified material medium contains as many positive electrons as negative. This force (P, Q, R) tends to produce electric separation in the element by moving them in opposite directions, leading to an electric current in the case of a conductor whose electrons are in part free, and to electric polarisation in the case of a dielectric whose electrons are paired into polar molecules. In the former case, the rate at which this force works on a current of electrons (u', v', w'), is $Pu' + Qv' + Rw'$; it therefore is identical with the electric force as ordinarily defined in the elementary theory of steady currents. In the case of a dielectric it represents the ordinary electric force producing polarisation. So long as a current is prevented from flowing, the ponderomotive force acting on the element of volume of the medium is the one of electrostatic origin due to such polarisation as the element may possess, for as the element is unelectrified it contains as many positive electrons as negative. But if a current is flowing, the first two terms of (P, Q, R), instead of cancelling for the positive and negative electrons, become additive, as change of sign of the electron is accompanied by change of sign of its velocity: so that there is an electrodynamic force on the element of volume,

$$(X, Y, Z) = (v'c - w'b,\ w'a - u'c,\ u'b - v'a),$$

where, however, (u', v', w') is the *true* current composed of moving electrons, not the total circuital current (u, v, w) of Maxwell, which includes the rotational displacement of the free æther in addition to the drift of the electrons.

The electric force (P, Q, R) as thus deduced agrees with the form obtained originally by Maxwell from the direct consideration of his concrete model of the electric field, with idle wheels to represent electrification. It has been pointed out by von Helmholtz and others, that the abstract dynamical analysis given in his *Treatise* does not really lead to these equations when all the terms are retained; this later analysis proceeds, in fact, by the use of current-elements, which form an imperfect representation, in that they give no account of the genesis of the current by electric separation in the element of volume of the conductor.

The ponderomotive force (X, Y, Z) is at right angles to the direction of the true current, and is precisely that of Ampère in the ordinary cases where the difference between the true current and the total current is inappreciable. It differs from Maxwell's result in involving true current instead of total current; that is, the forcive tends to move an element of a material body, but there is no such forcive tending to move an element of the free æther itself. In this respect it differs also from the hypothesis underlying von Helmholtz's recent treatment of the relations of moving matter to æther.

The theory is applied (1) to the determination of the electric and magnetic stresses in material media and of the mechanical pressure caused by radiation, (2) to optical propagation, including detailed theories of dispersion and metallic reflexion, including also the influence of motion of the material medium. It is shown that if electrons are accepted as the basis of material atoms, the latter topic is fully elucidated; also that the theory is not at a loss when explanations of the phenomena of inertia, gravitation and spectra are demanded.

June 20.—"An Inquiry into the Nature of the Vesicating Constituent of Croton Oil." By Wyndham R. Dunstan, F.R.S., and Miss L. E. Boole.

The vesicating constituent, or more strictly, the pustule-producing constituent of croton oil, has been the subject of investigation by numerous chemists and pharmacologists during the past forty years. According to the researches of Buchheim, and more recently of Kobert and Hirscheydt, the vesicating action is due to an acid closely allied to oleic acid, which has been given the name of crotonoleic acid. This substance is now prepared on a large scale in Germany for medical use, being extracted from croton oil by the method devised by Kobert and Hirscheydt. This consists in saponifying with barium hydroxide that part of croton oil which readily dissolves in strong alcohol. The resulting barium salts are washed with water, then dried, and repeatedly extracted with ether, which dissolves the barium salts of oleic and crotonoleic acids. These salts are separated by means of ether, which dissolves only the barium crotonoleate, and this, when decomposed with dilute sulphuric acid and extracted with ether, furnishes the crotonoleic acid as a viscid oil.

Since very little is known about this acid, even its composition being undetermined, the authors prepared it with the object of studying its properties and, if possible, of determining the constitution since no fatty acid of known constitution exhibits the property of vesicating. Starting with the crotonoleic acid

[1] Printed in abstract in NATURE, xlix. pp. 260, 280.

prepared as described above, the lead salt was obtained and submitted to a process of fractional precipitation by adding successive quantities of water to its solution in alcohol. By this means crotonoleic acid was proved to be a mixture composed for the most part of inactive oily acids, the lead salts of which are precipitated first, whilst the true vesicating constituent (or its lead salt) is principally contained in the last fractions, and represents but a small proportion of the original material. It was observed that the conversion of the crotonoleic acid into a lead salt did appreciably affect its vesicating power.

The supposed active constituent of croton oil, crotonoleic acid, having thus been shown to be a mixture, the authors proceeded to attempt to isolate the vesicating constituent from croton oil direct.

By saponifying that part of croton oil which is soluble in strong alcohol with a mixture of lead oxide and water, and repeatedly fractionating an alcoholic solution of the lead salts with water, the later fractions, which possessed the greatest vesicating power, ultimately furnished, when submitted to a series of fractionations, a resinous substance having extraordinary power as a vesicant. This substance could not be further resolved by repeating the process of fractional precipitation of the alcoholic solution with water. The same substance was isolated from the so called "crotonoleic acid," and the authors propose to name it "croton-resin." To its presence the vesicating property of croton oil is due. The composition of croton-resin is expressed by the empirical formula $C_{13}H_{18}O_4$. So far all attempts to crystallise it, or to obtain crystalline derivatives from it, have been unsuccessful. It is a hard, pale yellow, brittle resin, nearly insoluble in water, light petroleum, and benzene, but readily dissolved by alcohol, ether, and chloroform. When heated it gradually softens, and is quite fluid at 90° C. Croton-resin has neither basic nor acidic properties: it may be boiled with a mixture of lead oxide and water without being appreciably affected. Ebullition with aqueous potash or soda gradually decomposes it, destroying its vesicating power. The products of this action are several acids, some of which are members of the acetic series. By oxidation of the resin with nitric acid a mixture of acids is obtained. The constitution of croton-resin is therefore complicated, and its molecular formula would appear to be at least $(C_{13}H_{18}O_4)_2$ or $C_{26}H_{36}O_8$. Since it is not saponified by a mixture of lead oxide and water, and as no glycerol could be detected among the products of its decomposition by alkalis, it is not a glyceride, and as it does not react with hydroxylamine or phenylhydrazine or sodium bisulphite, it is probably neither a ketone nor an aldehyde. The evidence so far obtained points to the conclusion that the constitution of the vesicating constituent of croton oil may be that of a lactone or anhydride of complicated structure.

"On the Magnetic Rotation of the Plane of Polarisation of Light in Liquids. Part I. Carbon Bisulphide and Water." By J. W. Rodger and W. Watson.

The aim of this investigation is the determination in absolute measure of the magnetic rotation of liquids at different temperatures, the effect of the chemical nature of the liquid on this property, and its correlation with other physical properties.

The present communication contains a description of the apparatus and method of experiment, and the results obtained with the standard liquids, carbon bisulphide and water, for sodium light, in a magnetic field of constant intensity, and at different temperatures between 0° and the ordinary boiling point.

In the case of carbon bisulphide three different samples were used, and identical results were obtained with three separate coils. In the following table are collected the mean values of the boiling point (b. p.), density at 0° (ρ_0), and Verdet's constant at 0° (γ_0). Verdet's constant may be defined as the rotation in minutes of arc produced in a column of liquid when the difference between the magnetic potentials at the ends of the column is equal to one C.G.S. unit.

		B. p.	ρ_0.	γ_0.
CS_2 No. 1	...	46°·25	1·29271	0·04348
CS_2 No. 2	...	46·26	1·29282	0·04347
CS_2 No. 3	...	46·26	1·29283	0·04347

It will be seen that the three different samples give practically identical values for the three physical constants.

The results obtained for the rotation of carbon bisulphide may be summed up in the following equation, where γ_t is the value of Verdet's constant at the temperature t,

$$\gamma_t = 0{\cdot}04347\,(1 - 0{\cdot}001696t).$$

The expression connecting rotation and temperature is therefore linear.

In the case of water the results are best represented by

$$\gamma_t = 0{\cdot}01311\,(1 - 0{\cdot}0_4305t - 0{\cdot}0_5305t^2).$$

Here the rate of change of the rotation with temperature increases as the temperature rises.

In the case of water the quotient γ/ρ, where ρ is the density is practically constant up to 20°, it then very slowly *increases*, the rate of increase between 20° and 100° being practically constant.

For carbon bisulphide the quotient γ/ρ *decreases* at a constant rate as the temperature rises, the rate of decrease being very much greater than the rate of increase in the case of water.

The measure of the molecular rotation which is usually employed in chemical investigations is

$$(M\gamma/\rho)_{\text{substance}} / (M\gamma/\rho)_{\text{water}},$$

where M is the molecular weight. Although the authors postpone a detailed discussion of the validity of this expression, they show that for carbon bisulphide, at any rate, its value changes with the temperature, and hence the conclusions obtained by its use regarding questions of chemical constitution, especially of tautomerism, are affected on this account.

They also point out that the above expression involves the properties of water. The only justification for the use of water in relative observations is the elimination of variations in the strength of the magnetic field in which the observations are made. If the temperature of observation is always the same, this can readily be done. If, on the other hand, the temperature varies, it is essential to know how the rotation of water alters with the temperature. In the past this alteration was unknown, and the arbitrary measure of the molecular rotation above referred to has come into use. Since an expression for the temperature variation has now been obtained it is to be hoped that observers will employ a measure of the molecular rotation which does not involve the properties of water. Indeed, other considerations make such a measure all the more desirable. Up till now the authors have made observations on eight liquids, besides water and carbon bisulphide, and in all cases except that of water the relation between rotation and temperature is linear, and the quotient, rotation divided by density, diminishes as the temperature rises. It is highly probable, therefore, that as regards magnetic rotation, as in the case of so many other properties, the behaviour of water is exceptional, and hence it is particularly ill-suited for the use to which it has been put. Again, on account of the smallness of the rotation in water, the unavoidable inaccuracies in determining its rotation, and thus estimating the strength of the magnetic field, produce a larger percentage error in the results than if a liquid, such as benzene, having a considerably higher rotation than water, were used for this purpose.

Chemical Society, June 20.—Mr. A. G. Vernon Harcourt, President, in the chair. The following papers were read:—On the "isomaltose" of C. J. Lintner, by H. T. Brown and G. H. Morris. Lintner's isomaltose is shown to be merely impure maltose, and the isomaltosazone derived from it is maltosazone; maltose is the only substance produced in the diastatic conversion of starch which yields a crystallisable osazone.—Action of diastase on starch: nature of Lintner's isomaltose, by A. R. Ling and J. L. Baker.—The transformation of ammonium cyanate into urea, by J. Walker and F. J. Hambly. The velocity of interconversion of urea and ammonium thiocyanate under various conditions in aqueous solutions has been quantitatively studied; the numbers obtained can be interpreted by the dissociation hypothesis.—Note on the transformation of ammonium cyanate into urea, by H. J. H. Fenton.—Some derivatives of humulene, by A. C. Chapman. A number of derivatives of humulene, the sesquiterpene contained in the essential oil of hops, are described.—Note on thio-derivatives from sulphanilic acid, by Miss L. E. Walter. The parasulphonate-xanthate, $SO_3K.C_6H_4.S.CS.OEt$, obtained by the interaction of potassium xanthate and diazotised sulphanilic acid, is readily converted into derivatives of the sulphydride, $SO_3K.C_6H_4.SH$, a number of which are described together with their oxidation products.—Helium, a constituent of certain minerals (part ii.), by W. Ramsay, J. N. Collie, and M. Travers. Fifteen out of about thirty minerals studied were found to yield helium, the density of the several samples of gas examined being about 2·2; the wave-length of sound in the gas corresponds to 1 : 1⅔, so that the atomic weight should be 4·4. Helium has the solubility 0·007 in water at 18°, and is hence the

least soluble gas known.—New formation of glycollic aldehyde, by H. J. H. Fenton. The acid, $C_4H_4O_6.2H_2O$, previously prepared by the author, yields glycollic aldehyde when heated with water: the aldehyde readily polymerises, yielding an amorphous hexose, $C_6H_{12}O_6$.—Ethereal salts of ethanetetracarboxylic acid, by J. Walker and J. K. Appleyard.—On the occurrence of argon in the gases enclosed in rock salt, by P. P. Bedson and S. Shaw. The nitrogen given off by the Middlesburgh brine contains about the same proportion of argon as does atmospheric nitrogen.—On the dissociation of gold chloride, by T. K. Rose.—On some physical properties of the chlorides of gold, by T. K. Rose.—The dissociation of liquid nitrogen peroxide (part ii.); the influence of the solvent, by J. T. Cundall. The dissociation of nitrogen peroxide in solution is dependent on the temperature and on the nature of the solvent; solutions in fourteen "inactive" solvents have been quantitatively examined.—Condensation of benzil with ethylic acetoacetate, by F. R. Japp and G. D. Lander.—On a method for preparing the formyl derivatives of the aromatic amines, by H. R. Hirst and J. B. Cohen. The primary aromatic amines yield formyl derivatives when treated with formamide in acetic acid solution.—A modification of Zincke's reaction, by H. R. Hirst and J. B. Cohen. The condensation of aromatic hydrocarbons with benzyl chloride, chloroform, &c., is readily brought about by amalgamated aluminium foil.—A method for preparing cyanuric acid, by W. H. Archdeacon and J. B. Cohen. Cyanuric acid and hydrogen chloride are obtained on heating urea and phosgene in toluene solution at 230° in sealed tubes.—The oximes of benzaldehyde and their derivatives, by C. M. Luxmore.—On a colouring matter from *Lomatia ilicifolia* and *Lomatia longifolia*, by E. H. Rennie. A yellow colouring matter, which seems to be hydroxylapachol, is found adhering to the seeds of the two species of Lomatia.—The colouring and other constituents contained in Chay root (part ii.), by A. G. Perkin and J. J. Hummel. In addition to the constituents previously isolated from Chay root, the authors now describe a hystazarin monomethyl ether and the three anthragallol dimethyl ethers.—The six dichlorotoluenes and their sulphonic acids, by W. P. Wynne and A. Greeves.—The disulphonic acids of toluene and of ortho- and para-chlorotoluene, by W. P. Wynne and J. Bruce.—Contributions to our knowledge of the aconite alkaloids. Part xii. The constitution of pseudaconitine: preliminary notice, by W. R. Dunstan and F. H. Carr.

PARIS.

Academy of Sciences, July 15.—M. Marey in the chair.—Researches on the electric discharge of the torpedo, by M. d'Arsonville. The author has investigated this discharge by means of self-registering apparatus, and has rendered it apparent by passing the current through various dispositions of a set of small incandescent lamps. At 10° C. the mean duration of a discharge is from 0·1 to 0·05 second. With torpedos from 25 to 35 cm. in diameter, kept for eight days in the laboratory basins, the E.M.F. oscillates between 8 and 17 volts, and the intensity between 1 and 7 amperes. There is no difference of potential between the two faces of the organ in repose. The two organs function synergically and with the same intensity, each organ having several sections giving independent discharges. During a discharge, the organ rises from 0·2° to 0·3° in temperature if short-circuited, but does not become heated if in open circuit. The electricity is produced in the organ itself, and not in the nerves serving it. M. Marey followed up this paper with a few appreciative remarks, emphasising the author's point that new light on the nature of muscular action might be expected from [illegible] on the electric organs of the torpedo, and [illegible] that the author intends studying the effect of certain [illegible] physical agents of which the action on muscles is [illegible].—On a bed of potassium and aluminium phosphate [illegible] in Algeria, and on the genesis of these minerals, by M. Ad. Carnot.—Calculation of fluid trajectories, by M. [illegible].—A comparison between electric motors with continuous currents and those with alternating currents, by M. [illegible].—On the absorption spectrum of liquid air, by Profs. Liveing and Dewar. Janssen's law that the intensity of the bands increases as the square of the density of oxygen would appear to indicate that these particular bands are due either to complex molecules produced by condensation, or to the encounters of molecules of ordinary mass, encounters which are more frequent as their free path is diminished. An examination of the absorption spectrum of liquid air and comparison with that of liquid oxygen under ordinary pressures shows that a thickness of 0·4 cm. of liquid oxygen gives a much greater band intensity than 1·0 cm. of liquid air. The bands in the liquid air spectrum become more intense as the nitrogen boils off. Mixtures of liquid air and oxygen confirm Janssen's law at low temperatures. Solid air, whether containing solid oxygen or not must remain doubtful, shows practically the same character and intensity of absorption as liquid air, hence the encounter theory is not borne out by experiment.—Action of the infra-red rays on silver sulphide, by M. H. Rigollot. Using silver sulphide as an electrochemical actinometer, its sensitiveness to infra-red rays has been recognised far beyond the last visible radiations. The E.M.F. produced may possibly be due to a calorific action.—On the detection and presence of laccase in plants, by M. G. Bertrand. Laccase has been recognised in many plants; a list is given. It appears only to be found in the rapidly developing parts, the older portions of plants not yielding this diastase-like substance.—On the essence of Linaloë, by MM. Ph. Barbier and L. Bouveault. This essence consists essentially of licareol with small quantities of a sesquiterpene, of licarhodol, and diatomic and tetratomic terpenes, together with 0·1 per cent. of a ketone, $C_9H_{14}O$.—On the penetration of embryos of "l'anguillule stercorale" into human blood and the relation between the presence of these embryos and certain fevers of hot countries, by M. P. Teissier.—On a transition form between cartilaginous and osseous tissues, by M. Joannes Chatin. The Gecko (*Platydactylus fascicularis*, Daud.) has furnished the tissue described.—On pelagic fishing in the deep sea, by MM. L. Boutan and E. P. Racovitza. The author is not able to confirm the existence of types specially adapted for life at great depths. He gives a list of forms found at from 400 to 500 metres below the surface, and shows that they are nearly the same as the forms asserted by Chun to be characteristic of great depths (1400 metres); the same types have even been collected near the surface. M. de Lacaze-Duthiers made some remarks on this paper, and particularly called attention to the suitability of the Banyuls station for this kind of work.—The phenomena of karyokinesis in the Uredineæ, by MM. G. Poirault and M. Raciborski.

LINEAR DIFFERENTIAL EQUATIONS.

Handbuch der Theorie der linearen Differentialgleichungen. Von Prof. Dr. Ludwig Schlesinger, Privatdocenten an der Universität zu Berlin. Erster Band. (Leipzig: Teubner, 1895.)

DE MORGAN is reported to have said of the subject of differential equations, that it illustrated the proverb that he who hides knows how to find. This was true enough at a time when the sole aim of the analyst was to "solve" differential equations by reducing them to quadratures, or to construct ingenious puzzles for the benefit of undergraduates. Integration by series was known, of course; but this was regarded as a mean device, useful indeed for purposes of calculation, especially to the physicist, but unworthy of the serious attention of the pure mathematician.

A new era began with the foundation of what is now called function-theory by Cauchy, Riemann, and Weierstrass. The study and classification of functions according to their essential properties, as distinguished from the accidents of their analytical forms, soon led to a complete revolution in the theory of differential equations. It became evident that the real question raised by a differential equation is not whether a solution, assumed to exist, can be expressed by means of known functions, or integrals of known functions, but in the first place whether a given differential equation does really suffice for the definition of a function of the independent variable (or variables), and, if so, what are the characteristic properties of the function thus defined. Few things in the history of mathematics are more remarkable than the developments to which this change of view has given rise. Leaving out of account the theory of partial differential equations, which is still beset with many and serious difficulties, it is not too much to say that in the course of less than half a century the theory of ordinary linear differential equations alone has attained a degree of extent and importance which makes it comparable with almost any of the main branches of analysis.

The landmarks of the new departure are the memoir of Briot and Bouquet in the *Journal de l'École Polytechnique* (cap. 36), Riemann's paper on the generalised hypergeometric series, and Fuchs's memoir in the sixty-sixth volume of *Crelle's Journal.* Since the publication of this last work, more especially, the progress made has been exceedingly rapid: the general principles of the subjects have been permanently established, so as already to admit of methodical treatment, and numerous particular applications, all of great interest and beauty, have attracted and continue to invite the attention of mathematical explorers. Thus there is the problem of discovering whether a given equation has an algebraic integral, and, if so, of finding it; there is the theory of equations with doubly periodic coefficients; and there is the theory of differential invariants. Each of these is associated with some of the most brilliant discoveries of modern analysis, and each offers abundant opportunity for further research.

The wide extent of the subject, and the immense number of memoirs relating to it, have created an urgent need for systematic treatises to serve as an introduction to the theory, and presenting its main outlines in a proper perspective. Fortunately this want seems likely to be supplied before long; various excellent works, dealing wholly or in part with linear differential equations, have recently appeared or are in course of publication, and among these the book now under review will take an honourable place.

Dr. Schlesinger's work, to be completed in two volumes, is intended to give a coherent and comprehensive account of the theory in the light of its most recent developments. This first volume is divided into eight sections, exclusive of two introductory chapters, one historical, the other treating of the existence of an integral, and the general nature of the singular points. Of the eight sections, the first contains the first principles of the theory, mostly after Fuchs; the second discusses systems of independent integrals, reduction when particular integrals are known, Lagrange's adjoint equation, non-homogeneous equations, and Frobenius's theorems on irreducibility; the third relates to the fundamental equation; the fourth to unessential singular points; the fifth to equations of the "Fuchsian" class, that is to say, of which the coefficients are rational functions of x and all the integrals are regular; the sixth treats of the development of integrals within a circular annulus; and, finally, the seventh and eighth contain the general theory of equations with rational coefficients.

The treatment is entirely analytical, and is based principally on the methods of Weierstrass as expounded by Fuchs, Frobenius, Hamburger and others; thus the integrals are obtained in the form of power-series valid within a certain region of the plane of the complex variable, and no use is made of geometrical diagrams such as those employed by Schwarz, Klein, and Goursat. Moreover, except in the fifth section, which contains a brief discussion of Riemann's P-function and of the hypergeometric series, the author confines himself to the *general* theory, and does not consider special cases, or particular applications. The demonstrations, for the most part, are concise, and free use is made of the sign of summation and double suffixes. For these reasons the book is perhaps hardly suitable for those who are approaching the subject for the first time; but any one who has read, let us say, Goursat's thesis on the hypergeometric series, or Klein's lectures on linear differential equations of the second order, and is moderately familiar with the Weierstrassian function-theory, will be able to consult it with advantage. To those who are engaged in research, Dr. Schlesinger's treatise will be of great value, because those parts of the subject which are included within the author's plan are discussed with sufficient thoroughness, with a consistent notation, and in logical order; while the analytical table of contents gives references to the original sources in direct connection with the articles of the book which are based upon them. It is rather a pity, by-the-by, that the dates have not always been given in these references; the reader may very possibly wish to know the date of a paper, and not be able to consult the volume of the journal in which it appeared.

Mathematicians will look forward with interest to

P

the appearance of the concluding volume of the treatise, which will contain, *inter alia*, a discussion of the group of an equation, and of the classification of equations according to the nature of the groups belonging to them. Until the work is complete, it is premature to express an opinion as to the degree of success with which the author has attained the object he has in view; but there can be no doubt of the valuable service which is rendered to science by the composition of a methodical treatise like this. So far as we are able to judge, account has been taken of all the most important researches which come within the scope of the present volume; the three last sections, in particular, include an account of the recently published papers of Helge von Koch, Poincaré, and Mittag-Leffler.

The proof-sheets appear to have been very carefully revised, so that the book is happily free from the crowd of misprints with which mathematical text-books, otherwise excellent, are not unfrequently disfigured. G. B. M.

THE RESEARCHES OF TESLA.

Inventions, Researches, and Writings of Nikola Tesla. By Thomas Commerford Martin. (New York: *The Electrical Engineer*, 1894.)

We have here an account of Nikola Tesla, his scientific inventions and work, by a devoted admirer. Mr. Martin is not a Boswell, and from the nature of the case his book could hardly have about it all that human interest which pervades the life and achievements of a veteran discoverer in science. Mr. Tesla is a young man whose career has been somewhat romantic, and whose ingenuity is such as to rank him very high indeed among the electrical workers and discoverers of the day. Born in Austro-Hungary, educated at the Realschule at Carstatt and the Polytechnic at Gratz, and professionally first in the Government Telegraph Department, and afterwards in Paris, his career as an engineer really began when he arrived in America little more than ten years ago.

In two or three years from the day on which he took off his coat in the Edison Works, Tesla motors had attracted attention, and he leaped at once to a position as a successful experimenter and inventor, which his subsequent work has only secured and made more important. His researches on the effects of alternating currents of high potential and frequency, in particular, though they had the misfortune to be made the subject of the speculations of the ordinary journalist, are of great scientific interest, and continued by Mr. Tesla himself and the army of enthusiastic workers we now have, cannot fail to yield theoretical results and practical applications which will more than fulfil the anticipations of those who took a sober and rational view of their possibilities. None of those who listened to Mr. Tesla at the Royal Institution will soon forget the almost [illegible] experiments performed, their clear exposition in what was to the lecturer manifestly a foreign language, and the enthusiasm which the results displayed excited in those present who were best able to judge of their scientific interest and importance.

Mr. Martin's account of Mr. Tesla's work is interesting, and yet perhaps it might have been in some respects better than it is. He has had excellent materials, such as the various lectures delivered by Mr. Tesla on his researches generally, the papers read from time to time to scientific societies on particular inventions and points of interest, and apparently the specifications of Mr. Tesla's patents. Our complaint, if we have one, is that this material has hardly been sufficiently worked up. Many of the lectures and papers were, as was inevitable, hurriedly composed, and the expression of Mr. Tesla's theoretical views contained in them is not always so clear and complete as it might have been made by one not so rapidly carried forward by the stream of discovery. A great inventor can hardly be expected to spend time weighing words and phrases, at any rate he has a title to be excused from doing so, which others who expound him do not possess. As it is, Mr. Martin's book is on the whole a reproduction of articles which appeared from time to time in the *Electrical Engineer* (of New York), and all we wish is that he could have spared the time and trouble necessary to cast the matter into a more homogeneous and symmetrical form.

For the lectures which are reproduced we are very grateful. They give Mr. Tesla's own description of his inventions, and his views on points of theory—views, which if not always orthodox, and sometimes expressed in language which appears strange, are always fresh and suggestive. The unavoidable repetitions of the same ideas, and recurring descriptions of the same apparatus, are not without some advantage, though they interfere with the unity of Mr. Martin's book, as they enable the lecturer's meaning to be made out more completely than would otherwise be possible.

The book is divided into four parts: Polyphase currents; Tesla effects with high frequency and high potential currents; miscellaneous inventions and writings; early phase motors and the Tesla oscillators. The two first parts are of course much more interesting than the remaining two, which have to do with such things as oil condensers, anti-sparking dynamo brushes, unipolar generators, the Tesla exhibit at the World's Fair, and the Tesla mechanical and electrical oscillators.

The discussion of polyphase currents, which occupies the first 115 pages of the book, has more unity of treatment about it than the second part, which consists mainly of the lectures Mr. Tesla delivered in this country and America. After a short introductory and biographical chapter, Mr. Martin proceeds to expound the principle of the rotating magnetic field and the construction of synchronising motors. A paper by Tesla, on a "New System of Alternate Current Motors and Transformers," is reproduced in this connection, and contains the foundation on which is based the remaining twenty-one chapters which make up Part i. These contain numerous modifications of the original idea, many of them exceedingly ingenious. A motor "depending on 'magnetic lag' or hysteresis" is described in Chapter xii. The peculiarity of this is stated in an introductory paragraph to be "that in it the attractive effects or phases, while lagging behind the phases of current which produce them, are manifested simultaneously and not successively." This statement itself seems to want some little exposition, though the arrangement is really very simple. An iron disc is pivoted within a fixed coil, wound just

large enough to admit the diameter of the disc one way, and a little more than its thickness the other. The coil carries two pole-pieces, one at each end, which project from opposite sides a little way round the disc. Thus opposite poles are stretched out as it were from the coil round the disc in the same direction. An alternating current passed round the coil magnetises both these pole-pieces and the disc, and the repulsion between the adjacent similar polarities of the disc and pole-pieces produces the rotation, the polarities of both being of course reversed with the current. The disc is wound with closed coils, so that the induced currents augment the turning couple developed. This arrangement is further developed into a "multipolar motor"; but in neither case is there any clear statement of how the action depends on hysteresis.

In connection with these and similar devices it would have been interesting to have had some estimate of efficiency, but generally speaking, in no part of the book is there any discussion of this most important question. Indeed, when the word energy is used it seems to bear a somewhat peculiar sense. For example, at p. 81 we have a statement as to the "energies" of the field and the armature, and the importance of these being equal if for a given sum the motor is to have the greatest efficiency. This passage is a little difficult of interpretation, if the word energy is to be taken as it ought to be in its technical sense throughout, though it is not very hard to make out the idea intended.

By far the most interesting portion of the book to a student of electricity generally is Part ii. The alternator of high frequency which Mr. Tesla used is fully described, and the arrangements for using it explained in the first of the lectures already referred to. The phenomena produced are set forth in the remaining chapters with numerous illustrations which render the descriptions very easy to follow. The whole subject of high frequency phenomena is very intimately connected with the researches of Hertz on the one hand, and the work of Mr. Crookes on the other, and forms a most inviting field of research for experimentalists who possess the necessary equipment. Whether always the theoretical view taken by Mr. Tesla is correct, is matter for legitimate difference of opinion. For one thing, we do not think that there is any difference at all between electric force produced by what is properly called electrostatic action and that produced by electro-magnetic action. The distinction is only mathematical the former force can be derived from a potential function, the latter cannot—and in a sense only expresses our ignorance of the mode of production of the force. But perhaps we are mistaken in supposing that Mr. Tesla regards the electric forces in these two cases as different in nature.

To every physical inquirer the perusal of these lectures cannot but be of the greatest benefit. It will again remind him that the field of research is unlimited, and quicken his scientific enthusiasm, if not to taking part in the work of this particular part of it, to at least prosecuting with renewed vigour the inquiry, whatever it is, which lies ready to his hand.

It was reported a few weeks ago that all the apparatus and machinery belonging to Mr. Tesla had been destroyed by fire. Every reader of his researches must sincerely sympathise with Mr. Tesla in his loss of valuable appliances and still more valuable time. That he at once set himself to repair the loss is only what was to be expected from his character; let us hope that it may result in such improvements of his means of experimenting as may, in some measure at least, make up for his disappointment, if it is not, what is perhaps too much to suppose, turned into a blessing.

A. Gray.

OUR BOOK SHELF.

An Introduction to Chemical Crystallography. By Andreas Fock, Ph.D., translated and edited by William J. Pope, with a preface by N. Story-Maskelyne, M.A., F.R.S. Pp. 189 and xvi. 8vo. (Oxford: Clarendon Press, 1895.)

This little book is issued by the Clarendon Press as a companion volume to Maskelyne's "Morphology of Crystals," which was recently reviewed in these columns. It is far from being a mere translation of Fock's "Einleitung in die chemische Krystallographie," which was published in 1888. That book contained a useful summary of the leading facts known about the origin and growth of crystals, and the general relations between their chemical composition and other properties, especially as regards isomorphism and the properties of mixed crystals. All this is contained in the present volume, which is, moreover, less sketchy than the earlier book, and the somewhat numerous inaccuracies which disfigured the German edition have been corrected. But it is in the additional matter that the chief alteration is to be found. About fifty pages have been introduced, containing a survey of those important contributions to our knowledge of crystals which have recently been made from the side of physical chemistry; the remarkable theoretical researches of Van t'Hoff and Willard Gibbs, and the quite recent experimental investigations of Bakhuis Roozeboom, to which they gave rise, are here very happily summarised and brought within the reach of the English elementary student.

In order to give a comprehensive survey of the origin and growth of crystals, it is necessary to take into account the properties of the solutions from which they separate, and several chapters are accordingly devoted to such subjects as the relations between osmotic pressure and concentration, the separation of double salts and those containing water of crystallisation, the conditions of equilibrium in a solution containing various *solutes* (to employ a convenient word suggested by Prof. Maskelyne in his preface as a term for the substances dissolved), and the resulting variations in the isomorphous mixtures which crystallise from such solutions; all these are subjects of great importance, which have up to the present time met with no adequate treatment in English text-books.

A treatise which merely summarises without criticism loses much piquancy and interest, and also some value as a guide to students. This objection may fairly be urged against Fock's book, which appears to accept without question all the observations reported by the author. It would have been better, for example, to indicate the insecure nature of some of the evidence which rests only upon microscopical observation, such as that of Lehmann and Vogelsang.

This book remains, nevertheless, an excellent survey of chemical crystallography, brought fully up to date, and one which will, we hope, open the eyes of English chemists to a new field of work.

Mr. Pope's translation is both fluent and accurate; he is further responsible for some of the new matter introduced into this edition. The book is lucid, readable, and interesting, and is one which does credit to the Clarendon Press.

Laboratory Exercises in Botany. By Prof. Edson S. Bastin, A.M. Philadelphia: W. B. Saunders, 1895.

For a laboratory manual this book is of great extent, for it includes more than 500 octavo pages, with no less than 87 plates. Yet it is more remarkable for what is omitted than for what is contained in it.

The first half of the book is devoted to organography, and consists of descriptions of the gross structure of a number of types of flowering plants, fully illustrated in the first 37 plates. This part of the book seems to us decidedly well done.

The second half, with 50 plates, is on vegetable histology. Strange to say, it deals simply and solely with the *vegetative* structure of phanerogams and vascular cryptogams. This branch of the subject is illustrated in great detail, and the anatomical work is sound, if not quite up to the highest modern standard.

Not a word, however, is said as to reproduction, development, or life-history. The words *pollen-tube, ovule, embryo-sac, archegonium, antheridium*, and *growing-point*, are sought in vain in the index, nor have we found any reference to them in the text, except that ovules are of course mentioned in the descriptive part. In fact, just those subjects which are most important in a scientific course of laboratory work are entirely passed over. The utter absence of any account of the lower cryptogams is also astonishing, for there is no indication that a second volume may be looked for.

The author is professor at a pharmaceutical college, and this fact may help to account for the extraordinary unevenness with which he has treated his subject. Students of pharmacy in America are no doubt required to have some acquaintance with the external characters of the higher plants, and some anatomical training may also be expected of them, with a view to the identification of drugs. Beyond this it would appear that their botanical education is not meant to go. The author has expended great pains on his work, but its manifest one-sidedness renders it quite valueless as a scientific guide to laboratory botany. Students of pharmacy in England are happily accustomed to a very different system of botanical teaching.

D. H. S.

The Source and Mode of Solar Energy. By I. W. Heysinger, M.A., M.D. (Philadelphia: J. B. Lippincott and Co., 1895.)

On the strength of an acquaintance with popular astronomical literature, in many cases not up to date, the author of this work offers a theory which he states to be capable of interpreting all the phenomena presented to us in the heavens. Briefly, we are asked to believe that all interstellar space is filled with attenuated water vapour, and that this vapour is decomposed into its constituents by the electricity generated by the movements of planetary bodies; the oxygen remains on the planets, while the hydrogen goes to maintain the incandescence of the central suns. The author deals very ingeniously with many of the apparent difficulties, such, for example, as the absence of an atmosphere from the moon; but his anxiety to leave nothing unexplained, has occasionally demanded other assumptions, and led to self-contradictions. Thus, in regard to comets, it is necessary to suppose, from the repulsion of the tails, that when they enter our system, they do not behave electrically as planets do, but like suns, and so they should have hydrogen atmospheres; on the other hand, since carbon is assumed to be a "planetary" element (p. 69), they should not contain carbon. This is in complete contradiction with the facts. The author is so much behind the times in spectroscopic matters as to imagine that nebulæ abound in free nitrogen, and possibly oxygen, and that free nitrogen and hydrogen are characteristic of comets. It would serve no good purpose to discuss a theory based on such misconceptions.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Huxley Memorial.

I trust you will allow me through the medium of your columns to make it known that at the meeting of the Provisional Committee, which was held at the rooms of the Royal Society on Tuesday afternoon, it was announced that a large number of acceptances had already been received to the invitation which was issued a few days ago to a number of gentlemen to serve on the General Committee which it had been decided to form to inaugurate a National Memorial to the late Right Hon. T. H. Huxley, F.R.S.

A list of the Committee will shortly be published.

Owing to the lateness of the season, it has been decided to defer until after the autumn recess the meeting of the General Committee, at which the proposals of the Provisional Committee with regard to the form which the National Memorial shall take may be discussed and decided.

With a view of assisting the Provisional Committee in arriving at some general ideas on the subject, it is suggested that those who propose to contribute to the fund might be willing to inform the Treasurer of the probable amount of their subscriptions.

Subscriptions will be received and acknowledged by advertisement in *The Times* by the Treasurer, Sir John Lubbock.

J. D. Hooker,
Chairman of the Provisional Committee.

July 30.

The Kinetic Theory of Gases.

We shall all agree with Dr. Boltzmann's views as expressed in Nature of July 4, that if in a system of elastic sphere molecules the free paths be very long, and if at the same time the system be of unlimited extent, condition A will always be satisfied. The system will go on till it attains Nirvana in the Maxwell-Boltzmann distribution.

It is only for a finite system that it appeared to me that occasional disturbances from the outside were necessary to produce this result. I agree with Mr. Bryan that contact with the refrigerator or with the reservoir, such as is supposed to take place in thermodynamics, is for this purpose a disturbance.

But it is this very length of free path, and condition A which follows from it, that restricts our kinetic theory to the limiting case of a rare gas.

We have, as I maintain, to abandon condition A altogether if we wish to present our theory in a form applicable to dense media. We must consider, not single spheres, but groups of spheres to begin with. Given that there are at this instant n spheres, and no more within a spherical space S, but nothing is known of their position within S, what is the chance that their component velocities shall at this instant be

$$u_1 \ldots u_1 + du_1 \quad \ldots \quad \ldots \quad \ldots \quad w_n \ldots w_n + dw_n?$$

I assume that chance to be

$$C\epsilon^{-Q} du_1 \ldots dw_n,$$

in which $Q = a\Sigma(u^2 + v^2 + w^2) + b\Sigma\Sigma(uu' + vv' + ww')$, the summation including the n spheres and every pair of them. The coefficient b excludes condition A.

But whatever be the values of a and b, this distribution of velocities remains undisturbed by collisions. And by suitably choosing a and b, we can satisfy all other necessary conditions.

The same thing can be done for two sets of spheres of unequal masses m and m'. In that case we must put Q in the form

$$\begin{aligned} Q = {} & a\Sigma(u^2 + v^2 + w^2) + a'\Sigma(u'^2 + v'^2 + w'^2) \\ & + b\Sigma\Sigma(u_p u_q + v_p v_q + w_p w_q) + b'\Sigma\Sigma(u'_p u'_q + v'_p v'_q + w'_p w'_q) \\ & + \beta\Sigma\Sigma(uu' + vv' + ww'), \end{aligned}$$

in which the accents ′ refer to the m' set, and $\Sigma\Sigma u_p u_q$, &c., means summation over all pairs of spheres m, &c.

Here we have five coefficients, a, b, a', b', β. But the condition for permanence, notwithstanding collisions between m and m', requires

$$2am' - 2a'm + \beta(m' - m) = 0$$

$$b = \frac{m}{m'}\beta \qquad b' = \frac{m'}{m}\beta$$

three conditions reducing the five coefficients to two independent ones. It will be found that $mu^2 = m'u'^2$, as in the ordinary theory.

I doubt not that Boltzmann's minimum theorem can with some modification be applied to this system, at all events if he will take up the theory of dense gases himself.

S. H. Burbury.

On Skew Probability Curves.

In a memoir, entitled "Contributions to the Mathematical Theory of Evolution. II. Skew Variation in Homogeneous Material" (*Phil. Trans.* 186, A, pp. 343–414), and noticed in your columns by Mr. Francis Galton (January 31, 1895), I have dealt with four types of skew frequency curves.

Last Tuesday, Prof. Edgworth drew my attention to the fact that a portion of my results has been anticipated by Mr. E. L. De Forest in vols. vi., ix., and x. of *The Analyst*, an excellent American mathematical journal, the acquaintance of which, I am ashamed to say, I have only to-day made for the first time.

So far as Mr. De Forest's priority is concerned, it covers the special class of curve I have in my memoir termed Type III. He has fully worked out the geometry of this type, and I consider his deduction of it, if somewhat more lengthy than mine, to have the advantage of greater generality. So far as my own memoir is concerned, a knowledge of Mr. De Forest's memoir would not have led me to rewrite pp. 373–6 of mine, which deal with this type, because my discussion there is only a branch of my general treatment of a series of skew frequency curves. I should, however, have referred to Mr. De Forest's priority and the excellency of his work. In particular I should have cited the whole of his numerical table iii. x. p. 69, which gives the values of the frequency in excess and defect of the mode, and the probable errors in excess and defect, for a considerable range of values. These results are only given by algebraic or empirical formulæ in my paper. The statisticians among your readers, who may be proposing to deal with skew frequency, would find a copy of Mr. De Forest's Table III. of considerable service should they come across a curve of Type III.

Karl Pearson.

University College, London, July 24.

Evolution, or Epigenesis?

In the English translation of Prof. Hertwig's book "The Cell," it is stated (p. 295), "When the female gamete of the Alga *Ectocarpus* comes to rest, for a few minutes it becomes receptive. If the egg is not fertilised at this time . . . parthenogenetic germination begins to make its appearance . . . It may be accepted as a *law of nature* (italics mine) for mammals, and for the majority of other organisms, that their male and female sexual cells are absolutely incapable of development by themselves." Thus, what occurs in the lower organisms is no criterion of what occurs in the higher, and *vice versâ*. Then why does Hertwig remark (p. 348), "It is quite sufficient for our purpose to acknowledge, that in the plants and lower animals, all the cells which are derived from the ovum contain *equal quantities of the hereditary mass*. . . . All idioblasts must divide and must be transmitted to the daughter-cells, in *equal proportions both as regards quality and quantity*" (italics mine). According to the above, it is "quite sufficient" for Hertwig's purpose of discrediting Weismann's contention for differentiated distribution of hereditary elements among somatic cells, to show that there is undifferentiated distribution in the case of plants and lower animals. But, reverting to the earlier quotation, if it is not sufficient to prove sexual reproduction in the case of the higher organisms, in order to disprove parthenogenesis in the case of the lower organisms, why should it be "quite sufficient," in order to disprove distribution through germ-cells, in the case of the higher organisms, to show that, in plants and the lower animals one cell contains the same hereditary constituents as another? It is permissible to infer that differentiation in regard to germ-cells, in the higher animals, is no more disproved by the assumed demonstration that, in plants and the lower animals, there is no such differentiation, than that asexuality in lower is disproved by sexuality in higher organisms. Weismann, in my opinion, has proved to rational satisfaction that differentiation of germ from other cells must occur in the higher organisms, and he has offered a rational explanation, conformable with the theory of germ-plasm, of the apparently summational distribution of hereditary elements through somatic cells. Until Weismann's position is seriously undermined, which, so far, is not even a likely contingency, we must decline to accept Hertwig's assumed demonstrations in regard to plants and lower animals as invalidating the theory of germ-plasm. Similarly, that environment may affect the hereditary character of a primitive organism is no more evidence that it may so affect a mammal, than sexuality in the latter is evidence against parthenogenesis in the former. On page 348 we are told: "Johannes Müller has raised the question, 'How does it happen that certain of the cells of the organised body, although they resemble both other cells and the original germ-cell, can produce nothing but their like, *i.e.* cells which are (in-?) capable of developing into the complete organism? Thus epidermal cells can only, by absorbing material, develop new epidermal cells, and cartilage cells only other cartilage cells, but never embryos or buds.' To which he has made answer: 'This may be due to the fact that these cells, even if they possess the power of forming the whole, have, by means of a particular metamorphosis of their substance, become so specialised, that they have entirely lost their germinal properties, as regards the whole organism, and when they become separated from the whole, are unable to lead an independent existence.'" The above is simply a restatement of Weismann's doctrine regarding the origin of germ-cells. All cells which have not, as Müller states, "lost their germinal properties, as regards the whole organism," are Weismann's germ-cells.

So far as regards the essential question of heredity, Hertwig agrees with Weismann. Special units (idioblasts) are the bearers of hereditary qualities. This is "evolution," and no superstructural epigenetic thesis attributing modifying effects by environment, as the cause of a somatic cellular development, can affect the point that differentiation, through hereditary units, is the fundamental condition of morphological development. To accept "hereditary units," in my opinion, excludes "hereditary effect through environment," never mind to what matter-system the latter assumption be applied, whether the systems be, for instance, unicellular organisms or somatic cells. On the other hand, if we accept "hereditary extraneous influence," we need not trouble ourselves with "hereditary units." If "extraneous influences" have hereditary effect, "hereditary units" have no logical existence. All we then need for a theory of heredity are primordial homogeneous matter and environment. Mr. Herbert Spencer's earlier hypothesis, in which he attributed all variation to extraneous influence, would have been logical had he excluded "physiological units." With these, it became illogical. For this reason: if all organic variability depended on the effect of extraneous influences, why should such influences not have produced the differentiations called physiological units? Why should the only logical "unit" not be homogeneous *primordium*? That the conception "hereditary unit" shall be logical, involves that the "unit" shall be as unchangeable as an "atom." If, on the contrary, we have a variable "unit," it is not a genuine "hereditary unit," but merely the equivalent of any later variable "unit." Hertwig's "hereditary units," or "idioblasts" (p. 340), "are the smallest particles of material into which the hereditary mass or idioplasm can be divided, and of which great numbers and various kinds are present in this idioplasm. They are, according to their different composition, the bearers of different properties." They are not indivisible, like atoms, but assimilate food, grow and divide, as do Weismann's "biophors," from which they appear to differ only to the extent that they are complex organisms. The hereditary factor in Weismann's theory which corresponds with these "idioblasts" of Hertwig appears to be the "determinant." All the functions of the latter seem to be performed by the former. These "idioblasts" (p. 343) "must evolve in regular sequence during the process of development." As sentences are formed from words, so are organisms formed from these "idioblasts." We can attain a clear conception of the formation of sentences from words, but Hertwig does not enable us to apprehend how organisms can arise from "idioblasts." As he very truly observes (p. 344), "this portion of the theory is the most difficult to understand."

Hertwig, like Spencer, takes his stand on epigenesis. It may be asked, wherein is the epigenetic character of his (Hertwig's) theory? Unlike Spencer's "physiological units," Hertwig's "idioblasts" are intrinsically differentiated organisms with specific tendencies. Now, for a genuine epigenetic theory, hereditary units must merely compose a plastic mould to take the impress of environment, whereas these "idioblastic" cells are composed of elements with predetermined peculiarities. Accordingly they must function in a predetermined manner, and

thus the products of their activity must issue through evolutionary processes; what they will become after millions of generations must be determined so soon as these "idioblasts" combine as the first cell. If, however, we are to assume that the hereditary qualities of "idioblasts" can be eliminated by environment—as we must assume if we attempt to combine evolution with epigenesis—I reply, as in my earlier proposition, we have no need for "idioblasts" or any other "hereditary unit." All we then need for a theory of heredity is some plastic *primordium* and environment. Then, as such *primordium* would have no hereditary predisposition, there would be no room for predeterminism, and it would remain for ingenious theorists in love with epigenesis and the tape-measure system of estimating the cosmos, to explain the persistence of types under variable environment, and the differentiation of types under identical environment.

I can appreciate the eagerness of the "mechanical school" to welcome any loophole of escape from predeterminism. A genuine epigenetic theory is, no doubt, their great desideratum. If they "won't be happy till they get it," I venture to predict that they are doomed to a lengthened spell of dumps! The main issue raised by Hertwig in "The Cell," is: evolution or epigenesis? He tries to accept both, basing epigenesis on evolution. Thereby, in my opinion, he stultifies both doctrines. All biologists, so far as I am aware, start their theories from the basis of differentiated units. Equally they all evade the attempt to account for the differentiation. This omission I have endeavoured to rectify in "Rhythmic Heredity" (Williams and Norgate).

H. Croft Hiller.

A Sound-producing Insect.

In your issue of June 13, Mr. S. E. Peal speaks of a lepidopterous insect in Assam which makes a tapping noise when flying. His description so closely resembles an insect in Gorakhpur, that I think it must be identical or closely allied.

The alar expanse is about three inches. The wings are broad, not indented, of a very dark chocolate-brown colour on both sides, with one small yellowish-brown blotch on the costa of fore-wing on upper surface. The body is thin, like a butterfly, but the antennæ are not clubbed. It is apparently a Geometer or slender-bodied Bombyx. It flies in the darkest parts of woods, just as twilight is settling into night, and is very hard to see when standing up. By lying down, so as to get the sky as a background, it is easily visible. It cannot be netted in the ordinary way, as the eye cannot follow it, but by standing still till one is heard near, and then striking in the direction of the sound, one may sometimes be successful. I first succeeded in striking one down with my "solah topi"; afterwards I netted two, and brought them home alive, to see how the noise was made. The sound is a sort of clicking, which may be fairly imitated by striking the nails of the thumb and fore-finger together. From the thorax, between the bases of the wings, a stiff bristle (like a pig's) projects about a quarter of an inch. The noise is made by this bristle catching in the hind-margin of the fore-wings and the costal margin of the hind-wings. I fancy it must be of a warning character, as if the insect is eatable, it would help to enable bats and birds to find it. I think I have noticed that the insect is attracted by imitating the clicking sound with the nails, but could not satisfy myself on this point.

J. R. Holt.

A FEW MORE WORDS ON THOMAS HENRY HUXLEY.

TWO scenes in Huxley's life stand out clear and full of meaning, amid my recollections of him, reaching now some forty years back. Both took place at Oxford, both at meetings of the British Association. The first, few witnesses of which now remain, was the memorable discussion on Darwin in 1860. The room was crowded though it was a Saturday, and the meeting was excited. The Bishop had spoken; cheered loudly from time to time during his speech, he sat down amid tumultuous applause, ladies waving their handkerchiefs with great enthusiasm; and in almost dead silence, broken merely by greetings which, coming only from the few who knew, seemed as nothing, Huxley, then well-nigh unknown outside the narrow circle of scientific workers, began his reply. A cheer, chiefly from a knot of young men in the audience, hearty but seeming scant through the fewness of those who gave it, and almost angrily resented by some, welcomed the first point made. Then as, slowly and measuredly at first, more quickly and with more vigour later, stroke followed stroke, the circle of cheers grew wider and yet wider, until the speaker's last words were crowned with an applause falling not far short of, indeed equalling, that which had gone before, an applause hearty and genuine in its recognition that a strong man had arisen among the biologists of England.

The second scene, that of 1894, is still fresh in the minds of all. No one who was present is likely to forget how, when Huxley rose to second the vote of thanks for the presidential address, the whole house burst into a cheering such as had never before been witnessed on any like occasion, a cheering which said, as plainly as such things can say: "This is the faithful servant who has laboured for more than half a century on behalf of science with his face set firmly towards truth, and we want him to know that his labours have not been in vain." Nor is any one likely to forget the few carefully chosen, wise, pregnant words which fell from him when the applause died away. Those two speeches, the one long and polemical, the other brief and judicial, show, taken together, many of the qualities which made Huxley great and strong.

Among those qualities perhaps the most dominant, certainly the most effective as regards his influence on the world, were on the one hand an alertness, a quickness of apprehension, and a clear way of thinking, which, in dealing with a problem, made him dissatisfied with any solution incapable of rigid proof and incisive expression, he seemed always to go about with a halo of clear light immediately around him; and, on the other hand, that power of foreseeing future consequences of immediate action which forms the greater part of what we call sagacity. The former gave him his notable dialectic skill, and mark all his contributions to scientific literature: the latter made him, in addition, an able administrator and a wise counsellor, both within the tents of science and beyond. These at least were his dominant intellectual qualities; but even more powerful were the qualities in him which though allied, we distinguish as moral; and perhaps the greater part of his influence over his fellows was due to the fact that every one who met him saw in him a man bent on following the true and doing the right, swerving aside no tittle, either for the sake of reward or for fear of the enemy, a man whose uttered scorn of what was mean and cowardly was but the reciprocal of his inward love of nobleness and courage.

Bearing in mind his possession of these general qualities, we may find the key to the influence exerted by him on biological science in what he says of himself in his all too short autobiographic sketch, namely, that the bent of his mind was towards mechanical problems, and that it was the force of circumstances which, frustrating his boyish wish to be a mechanical engineer, brought him to the medical profession. Probably the boyish wish was merely the natural outcome of an early feeling that the solution of mechanical problems was congenial to the clear decisive way of thinking, to which I referred above, and which was obviously present even in the boy; and that it was not the subject-matter of mechanical problems, but the mode of treating them which interested him, is shown by the incident recorded by himself, how when he was a mere boy a too zealous attention to a post-mortem examination cost him a long illness. It is clear that the call to solve biologic problems came to him early; it is also clear that the call was a real one; and, as he himself has said, he recognised his calling when, after some years of desultory reading and lonely irregular mental activity, he came under the influence of Wharton Jones at Charing Cross Hospital. That made him a biologist, but con-

firmed the natural aptitude of his mind in making him a biologist who, rejecting all shadowy intangible views, was to direct his energies to problems which seemed capable of clear demonstrable proof. In many respects the biologic problems which lend themselves most readily to demonstrable solutions capable of verification are those which constitute what we call physiology; and if at the time of his youth the way had been open to him, Huxley would probably have become known as a physiologist. But at that time careers for physiologists were of the fewest. His master, Wharton Jones, a physiologist of the first rank, whose work in the first half of this century still remains of classic value, had been driven to earn his bread as an ophthalmic surgeon, and an even greater physiologist, William Bowman, was following the same course. There was no opening in physiology for the young student at Charing Cross, and he was driven by stress of circumstances to morphological rather than to strictly physiological problems; but it was not until long after, when he had achieved eminence as a morphologist, that he finally abandoned his old wish to hold a physiological chair.

Looking back on the past, we may now be glad that circumstances were against his wishes; for (though in every branch of science there is need at all times of a great man) there was at the middle of the century, in the early fifties, a special need in morphology for a man of Huxley's mould. Richard Owen was then dominant, and it is an acknowledged feature of Owen's work that in it there was a sudden leap from most admirable detailed descriptive labour to dubious speculations, based for the most part on, or at least akin to, the philosophy of Oken. Of the "new morphology" in which Johannes Müller was leading the way, and the criteria of which had been furnished by the labours of von Baer, there was then but little in England save, perhaps, what was to be found in the expositions of Carpenter. Of this new morphology, by which this branch of biology was brought into a line with other exact sciences, and the note of which was not to speculate on guiding forces and on the realisation of ideals, but to determine the laws of growth by the careful investigation, as of so many special problems, of what parts of different animals, as shown among other ways by the mode of their development, were really the same or alike, Huxley became at once an apostle. His very first work, that on the Medusæ, wrought out amid the distractions of ship life, written on a lonely vessel ploughing its solitary way amidst almost unknown seas, away from books and the communion of his fellow workers, bears the same marks which characterise his subsequent memoirs; it is the effort of a clear mind striving to see its way through difficult problems, bent on holding fast only to that which could be proved. This is not the occasion to insist in detail on the value of the like morphological work which he produced in the fifties and the sixties, or to show how he applied to other forms of animal life, to echinoderms, to tunicates, to arthropods, to molluscs, and last though not least to vertebrates, the same method of inquiry which guided the work on the Medusæ. Nor need I dwell on the many valuable results which he gained for science by attacking in the same spirit the problems offered by the remains of extinct forms. Moreover, he strengthened the effect of his own labours by admirable expositions of the results of others. Further, unlike his great predecessor who formed no school and had few if any disciples, it was Huxley's delight to hold out his hand to every young man whom he thought could profit by his help, and before many years were over his spirit was moving in the minds of many others. Thus it came about that during the latter half of this century, owing largely to Huxley's own labours and to the influence which he exerted not only in England but abroad, there has been added to science a large body of morphological truths, truths which have been demonstrated and must remain, not mere views and theories which may be washed away.

The excitement of the Darwinian controversy, with its far-reaching issues, has been apt to make us forget how great has been the progress of animal morphology during the past half century. Undoubtedly the solution of special problems touching animal forms, and the great theory of Natural Selection through the Struggle for Existence have been closely bound together: the special learning has furnished support for the general theory, and the general theory, besides strongly stimulating inquiry, has illumined the special problems. But the two stand apart, each on its own basis; and were it possible to wipe out, as with a sponge, everything which Darwin wrote, and which his views have caused to be written, there would still remain a body of science touching animal forms, both recent and extinct, acquired since 1850, of which we may well be proud. In the gaining that knowledge Huxley, as well by his own labours as by his influence over others, stands foremost, Gegenbaur being almost his only peer; and had Huxley done nothing more, his name would live as that of one of the most remarkable biologists of the present century.

As we all know, he did much more; his influence on England and on the world went far beyond that of his purely scientific writings. But when we reflect that a hundred years hence the image of the man as he went to and fro among men, so bright and vivid to-day, will have become dim and colourless, a shadow as it were, and that then the man will be judged mainly by the writings which remain, we must count these writings as the chief basis of his fame. And, though we may think it possible that the world of that day, much that is unwritten having been forgotten, may find it in part difficult to understand how great a power Huxley was in his time, the lapse of years will, we may be sure, in no way lessen, it may be will heighten, the estimate of his contributions to exact science.

As we all know, he did much more. To the public outside science he first became known as the bold, outspoken exponent and advocate of Darwin's views, and indeed to some this is still his chief fame. There is no need here to dwell on this part of his work, and I speak of it now chiefly to remark that the zeal with which he threw himself into this advocacy was merely a part of the larger purpose of his life. Science, or, to use the old phrase of the Royal Society, Natural Knowledge, had a two-fold hold on Huxley. On the one hand he felt deeply all the purely intellectual, and if we may use the word, selfish joys of fruitful progressive inquiry after truth. This was dominant in his early days, and to it we owe the long list of valuable researches, of which I just now spoke, and which followed each other rapidly in the fifties and the sixties. On the other hand, feeling deeply, as he did, his duties as a citizen of the world, science laid hold of him as being the true and sure guide to conduct man in all his ways; and this latter working of science in him, evident even in early days (witness his Address to Working Men at St. Martin's Hall in 1854), grew stronger and stronger as the years went on, until at last it took almost entire possession of him. To him, indeed, it may be said, science was all in all. He saw, as others see, in science a something which is broadening and strengthening human life by unceasingly bending nature to the use of man, and making her resources subservient to his desires; he saw the material usefulness of science, but he saw something more. He saw also, as others see, in science a something in which the human mind, exercising and training itself, makes itself at once nimble and strong, and dwelling on which is raised to broad and high views of the nature of things; he saw in science a means of culture, but he saw something more. He saw in science even as it is, and still more in science as it will be, the sure and trustworthy

guide of man in the dark paths of life. Many a man of science goes, or seems to others to go, through the world ordering his steps by two ways of thinking. When he is dealing with the matters the treatment of which has given him his scientific position, with physical or with biological problems, he thinks in one way; when he is dealing with other matters, those of morals and religion, he thinks in another way; he seems to have two minds, and to pass from the one to the other according to the subject matter. It was not so with Huxley. He could not split himself or the universe into two halves, and treat the one and the other half by two methods radically distinct and in many ways opposed; he applied the one method, which he believed to be the true and fruitful one, to all problems without distinction. And as years came over him, the duty of making this view clear to others grew stronger and stronger. Relinquishing, not without bitter regret, little by little, the calm intellectual joys of the pursuit of narrower morphological problems, he became more and more the apostle of the scientific method, driven to the new career by the force of a pure altruism, not loving science the less but loving man the more. And his work in this respect was a double one; he had to teach his scientific brethren, at least his biologic brethren, the ways of science, and he had to teach the world the works of science. It was this feeling which, on the one hand, led him to devote so much labour to the organisation of biologic science in order that his younger brethren might be helped to walk in the straight path and to do their work well. It was this feeling, on the other hand, which made him urgent in the spread of the teaching of science. It was this, and no vain love of being known, which led him to the platform and the press. The zeal with which he defended the theory of Natural Selection came from his seeing the large issues involved; to him the theory was a great example of the scientific method applied successfully to a problem of more than biologic moment; while the fierceness of his advocacy was a natural expression of resentment on the part of one who saw a scientific conclusion, gained with unstinted pains and large reasoning, judged contemptuously by men who knew nothing of science according to methods in which science had no part.

Science, under this aspect, is a part of what is sometimes called philosophy; and though Huxley felt, in common with others, and felt deeply the pleasures of the intellectual wrestler, struggling with problems which, seemingly solved and thrown to the ground, spring up again at once in unsolved strength, it was not these pleasures alone which led him, especially in his later years, to devote so much time and labour to technical philosophic studies. He hoped out of the depths of philosophy to call witnesses to the value of the scientific method. Indeed, nearly all the work of the latter part of his life, including the last imperfect fragment, written when the hand of disease which was to be the hand of death was already laid upon him, and bearing marks of that hand, was wrought with one desire, namely to show that the only possible solutions of the problems of the universe were such as the scientific method could bring. This was at the bottom of that antagonism to theology which he never attempted to conceal, and the real existence of which no one who wishes to form a true judgment of the man can ignore. He recognised that the only two consistent conceptions of man and the universe were the distinctly theologic one and the scientific one; he put aside as unworthy of serious attention all between. He was convinced that the theologic conception was based on error, and much of his old age was spent in the study of theologic writings whereby he gathered for himself increasing proof that there was no flaw in the judgment which had guided his way from his youth upward. Not only so, but he was no less convinced that, owing to what he believed to be the essential antagonism of the theologic and the scientific methods, the dominance of the former was an obstacle to the progress of the latter. This conviction he freely confessed to be the cause of his hostile attitude; he believed it to be the justification of even his bitter polemics.

But while on the objective side his scientific mode of thought thus made him a never-failing opponent of theologic thought of every kind, a common tie on the subjective side bound him to the heart of the Christian religion. Strong as was his conviction that the moral no less than the material good of man was to be secured by the scientific method alone, strong as was his confidence in the ultimate victory of that method in the war against ignorance and wrong, no less clear was his vision of the limits beyond which science was unable to go. He brought into the current use of to-day the term "agnostic," but the word had to him a deep and solemn meaning. To him "I do not know" was not a mere phrase to be thrown with a light heart at a face of an opponent who asks a hard question; it was reciprocally with the positive teachings of science the guide of his life. Great as he felt science to be, he was well aware that science could never lay its hand, could never touch, even with the tip of its finger, that dream with which our little life is rounded, and that unknown dream was a power as dominant over him as was the might of known science; he carried about with him every day that which he did not know as his guide of life no less to be minded than that which he did know. Future visitors to the burial-place on the northern heights of London, seeing on his tombstone the lines—

> "And if there be no meeting past the grave,
> If all is darkness, silence, yet 't is rest.
> Be not afraid ye waiting hearts that weep,
> For God still 'giveth his belovèd sleep,'
> And if an endless sleep He wills, —so best"—

will recognise that the agnostic man of science had much in common with the man of faith.

There is still much more to say of him, but this is not the place to say it. Let it be enough to add that those who had the happiness to come near him knew that besides science and philosophy there was room in him for yet many other things; they forgot the learned investigator, the wise man of action, and the fearless combatant as they listened to him talking of letters, of pictures, or of music, always wondering which delighted them most, the sure thrust with which he hit the mark whatever it might be, or the brilliant wit which flashed around his stroke. And yet one word more. As an object seen first at a distance changes in aspect to the looker-on who draws nearer and yet more near, features unseen afar off filling up the vision close at hand, so he seemed to change to those who coming nearer and nearer to him gained a happy place within his innermost circle; his incisive thought, his wide knowledge, his sure and prompt judgment, his ready and sharp word, all these shrunk away so as to seem but a small part of him; his greater part, and that which most shaped his life, was seen to be a heart full of love which, clinging round his family and his friends in tenderest devotion, was spread over all his fellow men in kindness guided by justice.

M. FOSTER.

DR. FRIEDRICH TIETJEN.

AT a time when astronomical knowledge is being extended at so rapid a rate, and in so many directions, as has been the case during the last few years, it is natural and right that the highest honour should be paid to those astronomers to whose genius and industry are due discoveries possible on account of original suggestion

or ingenious execution. But at the same time, and on the other hand, there is no small danger that we may fail to give proper recognition to those other astronomers whose lives, unmarked by brilliant achievements, have been devoted to labours which are none the less valuable because they have been accomplished while quietly pursuing recognised lines, and are therefore devoid of conspicuous originality. In particular, the work of computation and arithmetical reduction of observations, without which the observations themselves either cannot be made or must remain almost entirely useless, is apt to fall into disrepute, as being wholly mechanical and unenterprising. This is certainly to be regretted; for just as a victorious general marching forward in the enemy's country must depend for his very safety on the fidelity and capacity of those officers who hold the conquered territory, so our scientific knowledge is liable to become disconnected and fragmentary unless we have capable men ready to perform the task of computing from the observations, and co-ordinating the results achieved in more exciting spheres of scientific work. If the pursuit of such unostentatious work lead to the effacement of the worker, our gratitude should be even all the greater for the self-denial exhibited and practised. Of such a man we have recently had to lament the loss, owing to the sad death of Dr. Tietjen, of Berlin.

Friedrich Tietjen was born in Oldenburg, in the year 1834; we therefore lose his services at the comparatively early age of sixty-one. He studied mathematics and astronomy at Göttingen, and subsequently at Berlin, with which latter city he has been continuously connected. In 1861, he became attached to the staff of the Berlin Observatory, and in one or other capacity this connection remained unbroken till the time of his death. He was appointed Professor of Astronomy in the University of Berlin, and Director of the *Recheninstitut*, allied to the Berlin Observatory. In his earlier career, Dr. Tietjen occupied himself with the observations of comets and asteroids, discovering in this way the asteroid *Semele*. To his activity and devotion the pages of the *Astronomische Nachrichten* abundantly testify. He is also known as the calculator of several cometary orbits, and also of the orbits and ephemerides of many asteroids. Some twelve years later, Dr. Tietjen became superintendent of the *Berliner Astronomisches Jahrbuch*, and his reputation in that capacity is not less assured than that of Dr. Powalky, who had preceded him in that office. As official director he paid great attention to shortening the labour of the necessary calculations as far as possible. Some of his methods have been published, others are not so well known, ill-health having prevented him from giving them to the world. Of the value and of the accuracy of this publication under the superintendence of Dr. Tietjen it is unnecessary to speak here, for it is sufficiently well known. Probably his most useful work was that done in superintending the preparation of the ephemerides of the small planets, the continual and rapid increase in the number of which, while it enormously increased his work, had likewise the effect of lessening the interest in this class of discoveries. While the national almanacks of other countries practically discontinued the publication of this class of ephemerides, Dr. Tietjen loyally struggled to supply sufficient information to ensure the observation of the small planets. Those who have attempted the determination of the mass of Jupiter from the perturbations of these bodies, and similar kinds of work, know how to appreciate the labours of Dr. Tietjen, by which the continuous observation from opposition to opposition has been rendered possible.

This skilled mathematician and remarkably facile computer died at Berlin, on June 21, deeply lamented by his numerous friends, and regretted by many who have profited by the devotion of his quiet unambitious life to the service of astronomy.

THE MAXIM FLYING MACHINE.

On Friday, July 5, a large party of scientific men paid a visit, by invitation of Mr. Hiram Maxim and Mr. Brodrick Cloete, to Baldwyns Park, Bexley, to witness a trial of the celebrated flying machine, and the latest development in the direction of mechanical flight.

The invitations were carefully distributed among those who were competent to judge of the magnitude of the task to be attempted, and who were prepared to examine closely the ingenious mechanical details by which it was clearly demonstrated that the machine had ample power to lift itself off the ground, carrying with it a supply of fuel and water, and a crew for the navigation.

An unscientific crowd of spectators might have become unmanageable, and might have developed iconoclastic tendencies (like the Weser boatmen with Denis Papin's original steam vessel) when the machine did not take to flight immediately and disappear from their astonished gaze.

> "As lewed people demeth comunly
> Of thinges that ben maad more subtilly
> Than they can in her lewednes comprehende
> They demen gladly to the badder ende——"

But the Bexley machine is purposely designed of extreme size, with the intention of thoroughly testing and elaborating the details of the mechanism, and of measuring the lifting power, within immediate reach of a workshop and skilled mechanics, more than of actually taking to the air; this will probably be first attempted with a much smaller machine, capable of lifting one man, of jockey-like proportions, and mounted on a boat on a lake, so that short flights, like those of a flying fish, can be attempted for initial practice.

The lifting force of the machine is measured automatically as it runs along a railway track about half a mile in length, as shown in the accompanying illustration (Fig. 1), and the machine is prevented from taking to flight by wheels running underneath the outer wooden rails, seen in the figure; for much yet remains to be done in the way of practice in vertical steering before taking leave of the earth; the chief difficulties of the Aviator beginning when he wishes to descend and alight on the ground again.

Chaucer did not realise the difficulties of the problem when describing so jauntily the Bronze Horse in the Squieres Tale:—

> "This same stede shall bere yow ever-more
> With-outen harm, til ye be ther yow leste,
> Though that ye slepen on his bak or reste;
> And turne ayeyn, with wrything of a pin."
>
> "But whan yow list to ryden any-where,
> Ye moten trille a pin, stant in his ere—"
> "Bid him descend, and trille another pin,"
> "Trille this pin, and he wol vanishe anon."

The "wrything of a pin" is not inapt in describing the dominating gyrostatic brain of the Aviator, designed by Mr. Maxim to perform the vertical steering automatically.

The Bexley machine, complete with the water, naphtha fuel, and crew of three men on board, weighs 8000 lb.; and running at forty miles an hour with a pressure of 275 lb. per square inch, the engines develop 360-horse power, the thrust of the screws is 2000 lb., and the lifting effect of the aeroplanes and wings, 4000 square feet in area, is 10,000 lb.

A thrust of 2000 pounds at 45 miles an hour gives 240 thrust horse-power; or, with a speed of advance of the screw of 60 miles an hour, 320 indicated horse-power.

The total projected disc area of the screws is 500 square feet, each screw being nearly 18 feet in diameter, with a pitch of 16 feet; and thus requiring 330 revolutions a minute to give a speed of advance of 60 miles an hour.

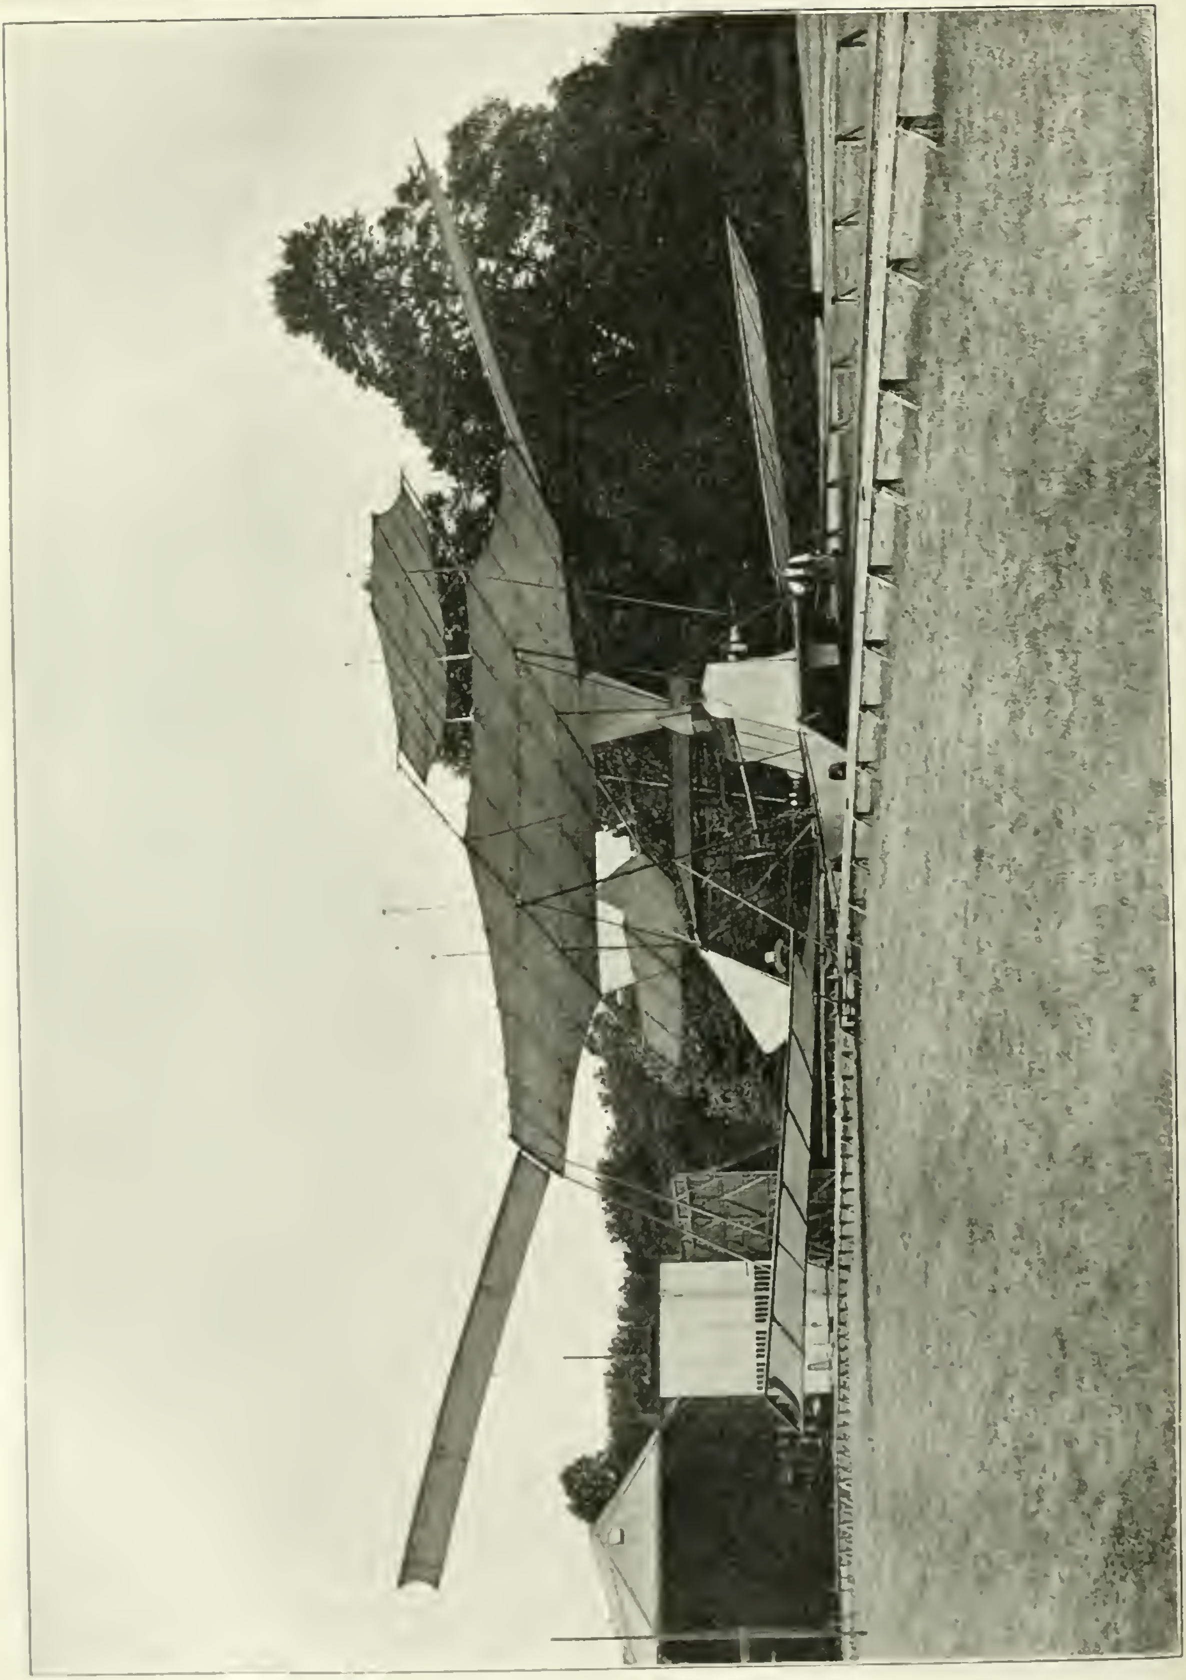

Fig. 1.—General view.

Fig. 2.—One of the screws, showing the connection with the engines.

Mr. Maxim calculates that, after making all allowances, he can at present lift 28 pounds per horse-power; but that, with improvements, he hopes to raise this figure to 50 or 60 pounds, and then a machine could take a flight of 500 or 600 miles.

When the machine is perfected, Mr. Maxim claims that the railway track may be dispensed with; and that a short run over a moderately level field will enable it to attain the velocity necessary to rise. As far as landing is concerned, he says that the aerial navigator will touch the ground while moving forward, and the machine will be brought to rest by sliding on the ground for a short distance. In this manner very little shock should result, whereas if the machine is stopped in the air and allowed to fall directly to the earth without advancing, the shock, though not strong enough to be dangerous (?) to life or limb, might be sufficient to disarrange or injure the machinery.

These numbers are taken from Mr. Maxim's lecture on "Experiments in Aeronautics," before the Society of Arts, November 28, 1894, where a full account of the mechanical details will be found. Each engine is a two-cylinder compound, with the cranks set at 180°; in this way the inertia stresses are self-contained, and racking of the framework is avoided; a similar arrangement is adopted by Mr. Thornycroft in his recent torpedo boats. A photograph showed Mr. Maxim lifting with ease one of these engines, from which 180-horse power can be developed. The boiler is, if possible, a still more wonderful miracle of lightness for its power, weighing only 1000 lb., and providing 360-horse power; the fire is given by a steel burner with 14,000 jets, made from the naphtha vapour delivered from an automatic gas generator. For details the reader must be referred to Mr. Maxim's lecture; but the chief result arrived at may be summarised as a performance of one-horse power for every 11 lb. of weight in the motor complete.

At this rate a 10-horse-power motor can be produced, which will weigh considerably less than an ordinary man; so that when Mr. Maxim can spare a little leisure from this fascinating problem of flight, he can beat easily the performance of the steam carriages recently competing in France, and carry off, we hope, the prize of £1000 offered in this country by the proprietors of the *Engineer*; and some day we may see his motor utilised for purposes of military traction, and galloping round the smartest battery of artillery on Woolwich Common.

Mr. Maxim eschews the gas bag of balloons and the use of vertical screws for securing levitation, and he relies entirely on the upward thrust on the aeroplane and wings, mounted at a slope of about 1 in 8, due to the currents of air rushing past them.

These surfaces are formed of canvas, stretched on a skeleton framework of hollow steel rods for the struts and thin steel wire for the ties; the large central aeroplane is composed of two parallel canvas surfaces, with a space between, and in this way the shape is preserved better, and the general set of the wings, smooth like cardboard, should excite the envy and stimulate the imitation of our sailmakers for yacht racing. The front and rear wings are shown pivoted about a horizontal axis, so as to act as rudders in a vertical plane.

The machine is started from the position in the photograph, being tied up to the indicator post shown in its rear; the propellers are then set in motion, and soon drive a gale of wind in their wake; when the pull of the rope has reached a definite amount, say 2000 lb., a hook is released, and the machine starts on its journey along the track. Mr. Maxim can now carry out his original notion of experimenting with a model machine, tied to a post in a gale of forty miles an hour, to be found every afternoon in the cañons of California, in an artificial gale produced in the wake of his propellers. Dynamometers register simultaneously the thrust of the propellers, so that much interesting information concerning the dynamics of screw propulsion can be obtained here, especially if Mr. Maxim will stretch a wire carrying ribbons across the axes of the propellers, in front and in rear, to measure the direction of the air currents. The speed in air Mr. Maxim deals with is about double the speed of the torpedo boat in water; but the effect of "cavitation" in water, which is beginning to trouble the naval architects, is one which will not concern the propeller working in air.

Now that the main mechanical difficulties of construction have been overcome, a longer track is required for the purpose of practice in vertical steering while the machine is off the ground, but bearing upwards against the outer rails. It is unfortunate that difficulties should have been thrown in the way of making an extension of the present track beyond the domain of Baldwyns Park; so another practice ground, perhaps a sheet of water, must be found, not too far from headquarters or from skilled assistance.

During a short interval of delay, caused by a refractory pump, an adjournment was made to a gravel-pit close by, to witness a performance of the Maxim automatic gun.

Ancient and mediæval mythology is full of references to flying machines, from Dædalus and his son Icarus, and Archytas of Tarentum, to

> "The story of Cambuscan bold
> . . . And of the wondrous horse of brass
> On which the Tartar king did ride"

of Chaucer's Squieres Tale; and to Johnson's "Rasselas," Peter Wilkins, Baron Munchausen, and Auber's opera "le Cheval de Bronze."

"Rasselas," chapter vi., "A Dissertation on the Art of Flying," is so curiously apposite that some extracts may well find a place here.

"Among the artists that had been allured into the Happy Valley, to labour for the accommodation and pleasure of its inhabitants, was a man eminent for his knowledge of the mechanic powers, who had contrived many engines, both for use and recreation." "This artist was sometimes visited by Rasselas, who was pleased with every kind of knowledge, imagining that the time would come when all his acquisitions would be of use to him in the open world. He came one day to amuse himself in his usual manner, and found the master busy in building a sailing chariot. He saw that the design was practicable upon a level surface, and with expressions of great esteem solicited its completion. 'Sir,' said the master, 'you have seen but a small part of what the mechanic arts can perform. I have long been of opinion that instead of the tardy conveyance of ships and chariots, man might use the swifter migration of wings, that the fields of air are open to knowledge, and that only ignorance and idleness need crawl upon the ground." "'The labour of rising from the ground will be great,' said the artist, 'as we see it in the heavier domestic fowls; but as we mount higher the earth's attraction and the body's gravity will be gradually diminished, till we arrive at a region where man shall float in the air without any tendency to fall; no care will then be necessary but to move forward, which the gentlest impulse will effect.' 'Nothing,' replied the artist, 'will ever be attempted if all possible objections must be first overcome. If you will favour my project I will try the first flight at my own hazard. I have considered the structure of all volant animals, and find the folding continuity of the bat's wings most easily accommodated to the human form. Upon this model I will begin my task to-morrow, and in a year expect to tower into the air beyond the malice and pursuit of man.'" "The Prince visited the work from time to time, observed its progress, and remarked many ingenious contrivances to facilitate motion and unite levity with strength. The artist was every day more certain that he should leave vultures and eagles behind him, and the contagion seized upon the Prince. In a

year the wings were finished, and on a morning appointed the maker appeared, furnished for flight, on a little promontory; he waved his pinions awhile to gather air, then leaped from his stand, and in an instant dropped into the lake. His wings, which were of no use in the air, sustained him in the water, and the Prince drew him to land half dead with terror and vexation."

These extracts show that Dr. Johnson had realised to some extent the difficulty of the problem to be solved; although Herr von Lilienthal's experiments, recently attempted by Prof. Fitzgerald, have to a certain extent falsified the universal application of his final catastrophe.

But, viewed with the cold calculating eye of mechanical science, the poetical descriptions are seen to be hopelessly absurd and impossible; now that Mr. Maxim has taken up the subject, and proved to demonstration the enormous power required, out of all proportion to the size, if man is ever to emulate the birds.

A. G. Greenhill.

NOTES.

The Organising Committee of the third International Zoological Congress, to be held at Leyden, September 16-21, has sent us a copy of the provisional programme. The programme contains some details with reference to the work proposed, not given in our previous notes on the forthcoming Congress. At the first general meeting, a discourse will be delivered by Dr. Weismann; Mr. Haviland Field's scheme for bibliographical reform will be reported upon by M. E. L. Bouvier; and a report on the prize instituted in 1892, at the Moscow meeting, will be made by M. Blanchard. At the second general meeting, Prof. Milne Edwards will give a discourse, and Dr. F. E. Schulze will propose the nomination of a commission of three members to draw up, in three languages, the code of zoological nomenclature. Dr. John Murray will address the third general meeting. With regard to the sections: up to the middle of July, the first section had been promised a communication on Weismanism, by M. A. Giard; on cellular theory, by Mr. A. Sedgwick; on Plankton studies, by Prof. Victor Hensen; and a paper by Dr. S. Apathy. Dr. Bowdler Sharpe will address Section II. upon the classification of birds; and there will be papers on the origin of the lacustrine fauna of European Russia, by Prof. N. Zograf (Moscow); on the fauna of Borneo, by J. Buttikofer; and on *Pithecanthropus erectus*, by Dr. E. Dubois. In the third section, Prof. W. Leche (Stockholm) will read an odontological paper, and there will also be papers by Prof. R. Semon (Jena) and Prof. O. C. Marsh. In the fourth section, papers referring to the classification of living and fossil invertebrates, and bionomy, will be read by Dr. V. Salensky, Dr. C. W. Stiles, M. Blanchard, and Prof. S. J. Hickson. The section of entomology has received papers by M. E. de Selys-Lonchamps, Father E. Wasmann, Dr. A. Fritze, and Prof. G. Canestrini. In Section VI., papers on the comparative anatomy and embryology of invertebrates will be read by A. de Korotnev, M. E. Perrier, Prof. J. W. Spengel, and Prof. Herdman. We understand that up to now the following delegates have been officially announced by the respective foreign Governments:—Belgium, Prof. Ed. van Beneden, Prof. Ch. van Bambeke, Prof. Gilson, and Prof. Lameere; France, Prof. Milne Edwards, MM. R. Blanchard, E. Bouvier, A. Certes, J. de Guerne, H. Filhol, Ch. Schlumberger, and L. Vaillant; Great Britain, Sir W. H. Flower, Prof. Sydney J. Hickson, Dr. J. Anderson, Dr. St. George Mivart, and Dr. P. L. Sclater; Sweden, Prof. F. A. Smith; Switzerland, Prof. Th. Studer, and E. Jung; United States (Department of Agriculture), Dr. C. W. Stiles.

A desire is widely felt among the pupils of Prof. Leuckart that the occasion of the fiftieth year of his doctorate should not pass without some durable mark of recognition from those who have known and valued his inspiring influence. It is proposed that the memorial should take the form of a marble bust, and an appeal for contributions is being circulated as widely as possible. There is naturally some difficulty in obtaining the addresses of all old pupils; and it is hoped that those who receive the appeal will make it generally known. Contributions should be sent to Herr Carl Graubner (C. F. Winter's Verlag, Leipzig, Johannes-gasse 8), who has consented to act as treasurer of the memorial fund.

It is proposed to honour Sir Joseph Lister by presenting his portrait to the Royal College of Surgeons for England, to be placed by the side of the portraits of John Hunter and other great surgeons of the past. On Tuesday last, in the presence of a large company, Sir Joseph was presented with a testimonial, in the form of a portrait of himself, subscribed for by his past colleagues and pupils, as a mark of esteem and admiration, on his retirement from the chair of clinical surgery at King's College Hospital.

The sixty-third annual meeting of the British Medical Association was opened on Tuesday, when Dr. E. Long Fox retired from the presidential chair, and Sir J. Russell Reynolds was installed as his successor. Dr. Ward Cousins, in moving the report of the Council, said that when they last met in London, in 1873, they numbered only 1500, whereas now their membership exceeded 16,000. The financial position of the Association is most satisfactory, the assets exceeding the liabilities by more than £60,000. In his opening address, Sir Russell Reynolds dwelt chiefly upon the great advances that have been made, during the past twenty years, in the elucidation of both structure and function—such, for example, as in the researches upon the thyroid, the adrenal bodies, the spleen, and the liver; the advance of bacteriology; the function of the axis-cylinder of nerves; and the development of a new field of therapeutics in the serum-treatment of disease.

The death is announced of Prof. H. Witmeur, Professor of Mineralogy and Geology in the University of Brussels, and of Prof. Josef Loschmidt, at Vienna.

Sir John Tomes, F.R.S., died at Caterham on Monday, at eighty years of age. He was elected into the Royal Society in 1850, after carrying out valuable work referring to dental physiology and surgery. In 1883, with the late Prof. Huxley, he was elected an honorary fellow of the Royal College of Surgeons; and three years later the honour of knighthood was conferred upon him, in recognition of his services to his profession.

We have already noted that an international conference for the protection of birds useful in agriculture, by helping to destroy injurious insects, has recently been held in Paris. Most of the countries in Europe were represented at the conference; and it was agreed that various measures should be taken to preserve useful birds, and to protect their nests and eggs from destruction. A list of birds considered useful has now been published by the Commission, and as this includes a number of our caged friends as well as other birds at present ruthlessly sacrificed for ornamental purposes, the trade in birds in various directions will naturally be curtailed. We learn from the *Revue Scientifique* that a period of three years is to be accorded to the different countries of Europe to allow them to arrange their laws in accordance with the principles agreed upon by the International Commission.

The prospectus is issued of a proposed complete directory of living botanists of all countries, inclusive of the officers of botanic gardens, institutes, and societies, as also of their works and the botanical papers issued by them. Any communication should be made to Herr J. Dörfler, III Barichgasse 36, Vienna, of the botanical section of the Imperial Museum of Natural History.

Mr. F. T. Coville, the honorary curator of the Department of Botany of the United States National Museum, issues an appeal for information on the aboriginal uses of plants by the natives of North America, accompanied by instructions as to the collecting of specimens, and the arrangement of the information under various heads.

We learn from the *Botanical Gazette* that the Division of Vegetable Physiology and Pathology in the United States Department of Agriculture has had under cultivation during the past year over 1000 varieties of wheat and oats. The grains have been collected from nearly all parts of the world, and have been grown chiefly for the purpose of obtaining information upon their rust-resisting qualities. Numerous crosses have been made, and material and facts obtained which will be used in further work.

A valuable memoir on the earthquakes of the Philippine Islands has recently been published by P. Miguel Saderra Masó, the director of the seismic section of the Observatory of Manila. The work consists of 122 quarto pages, and is illustrated by 48 plates, representing the instruments used in the observatory, the disturbed areas and isoseismal lines of sixty-one important earthquakes, and copies of some of the seismographic records, one of them somewhat resembling a bank manager's signature. With a seismological observatory so well equipped as that of Manila, a network of seismic and meteorological stations already established over the country, an energetic and capable director, and numerous shocks, the Philippine Islands promise to become as important a district for studying earthquakes as the neighbouring empire of Japan.

Some beautiful enlargements of phonograph traces are given by Dr. John G. McKendrick in the *Journal of Anatomy and Physiology*, illustrating his paper "On the Tone and Curves of the Phonograph." The accuracy of the phonograph records is strikingly exemplified by the traces of four Koenig tuning-forks, giving 64, 128, 256, and 512 vibrations per second respectively. In each case, the length of indentations is half of that of the previous set, and they are of the same character. Traces of the sounds of a violin, flute, organ, military band, and human voice, singing and speaking, are reproduced. But these traces do not show the exact motion of the vibrating disc. To exhibit this, the phonograph traces were converted into curves by a lever arrangement. The lever ended in a fine point of a hard needle, which translated the up-and-down motion of the reproducing style into a to-and-fro wave motion. To get rid of all disturbing vibrations due to the needle itself, the latter was firmly fixed in a lead block to which the reproducing style was attached, and the phonogram cylinder was turned so slowly that its motion was almost imperceptible to the eye. By this contrivance the uniform curves due to a tuning-fork, the smooth notes of a piccolo, the strong undulations of a bassoon, and the highly over-toned ripples of an old English coach horn were very effectively made visible to the eye.

A recent number of *Modern Medicine and Bacteriological Review* contains an article on Prof. Bunge's important paper on the therapeutic value of iron, read at the German Congress of Internal Medicine last spring. An interesting table is quoted showing the amount of iron found in various food substances. Spinach contains considerably more iron than the yolk of eggs, while the latter, again, is superior in this respect to beef, next in order coming apples, lentils, strawberries, white beans, peas, potatoes, wheat, etc., and almost at the bottom of the list we find cow's milk. That this article of food, of such great importance in infant life, should contain so small a quantity of iron, led Prof. Bunge to conduct a series of experiments on animals, to ascertain in what quantity iron was present in the system of animals of different age. The interesting fact was established that younger animals contain a much greater quantity of iron than adult animals, that the body of a rabbit or a guinea-pig, for example, one hour old, was found to contain more than four times as much iron as that of similar animals two and a half months old. Prof. Bunge is of opinion that a long-continued exclusive milk diet for infants is not advantageous, but should be supplemented by the addition of wheat preparations. Strawberries and apples, however, become invested with fresh attractions by the light of these investigations. The writer of the article suggests that reform is required in the administration of iron, and that the immense quantities of iron in the shape of tonics, which custom prescribes for patients, may very possibly, in a large number of cases, only serve to increase the discomfort of the invalid by the disturbance caused in the digestive functions of the body. In conclusion the hope is expressed that Prof. Bunge's valuable results will "set physicians to thinking more of materia alimentari.e, and less of materia medica"!

The *American Naturalist* for July contains a statement of the advantages offered for scientific study by the Missouri Botanical Garden at St. Louis, and by the Hopkins Seaside Laboratory, situated at Pacific Grove on the coast of California, and maintained by the Leland Stanford Junior University.

Quain's "Elements of Anatomy" (Longmans, Green, and Co.) is now in its tenth edition. The second part of the third volume, which has just been published, comprises the descriptive anatomy of the cerebro-spinal and sympathetic nerves, and their ganglia. It is by Prof. G. D. Thane, who, with Prof. Schäfer, edits the edition.

We have received the first part of a new monthly microscopical journal, the *Zeitschrift fur angewandte Mikroskopie*, edited by G. Marpmann, and published by Thost, of Leipzig. It will be especially concerned with technique and methods. The present number contains papers on a new species of *Scenedesmus*, by P. Richter; on modern imbedding materials, by the editor; on the fixing of spores and pollen in glycerin, by H. Reichelt; and a number of reviews and notes.

The Central Meteorological Institute of Finland has just issued vol. xii. (new series) of its observations for the year 1893. This service is one of the oldest, having been established about 1844, and reorganised, under the superintendence of the Society of Sciences of Finland, in 1882. Among its earlier publications there is a series of eye observations taken at twenty minutes interval, from March 1848 to December 1856, before the establishment of self-registering instruments, a labour which is probably without a parallel. The present volume contains hourly observations for Helsingfors, particular attention being paid to the character and motion of clouds, and to atmospherical electricity.

The eighth volume of the late Prof. Cayley's "Collected Mathematical Papers" has just appeared. The volume contains seventy papers, numbered from 486 to 555, published for the most part in the years 1871–73, and runs into 570 pages. In a prefatory note, Dr. A. R. Forsyth, the editor of this and the remaining volumes, says that Prof. Cayley had himself passed the first thirty-eight sheets for press, and prepared one note. The actual manuscript of this note, which was one of the last of Cayley's writings, is reproduced in fac-simile in the present volume, upon the kind of paper which he regularly used during his mathematical investigations. The remaining papers will appear without notes and references. The long biographical notice of Cayley, contributed by Dr. Forsyth to the *Proceedings* of the Royal Society, is reprinted in the volume just published.

The sixth annual report of the Missouri Botanical Garden bears witness that useful work was accomplished during last year.

In addition to the necessary routine work, several researches were carried out, and the results of some of these investigations are embodied in the report. Mr. M. A. Brannon, who occupied the Garden's table at the Wood's Holl Marine Biological Laboratory, has his studies on *Grinnellia* nearly ready for publication. The Director, Mr. W. Trelease, has made a large collection of the flora of the Azores, and is now working at it. The collection fully represents the flora of those islands, and adds somewhat to what is known of the distribution of species through the group. The papers included in the present report are:—"Revision of the North American Species of Sagittaria and Lophotocarpus," by Mr. J. G. Smith, who also describes a few new or little known species; "*Leitneria Floridana*," by Mr. Trelease. "Studies on the Dissemination and Leaf Reflection of *Yucca aloifolia* and other Species," by Mr. H. J. Webber; and "Notes on the Mound Flora of Atchison County, Missouri," by Mr. B. F. Bush. The report is illustrated by sixty excellent plates.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Captain Fitzgerald; a Common Marmoset (*Hapale jacchus*) from South-East Brazil, presented by Mrs. Florence Cowlard; a Serval (*Felis serval*), a White-necked Stork (*Dissura episcopus*), a Vociferous Sea Eagle (*Haliætus vocifer*), an Antarctic Skua (*Stercorarius antarcticus*) from Mozambique, presented by Mr. W. A. Churchill; a Cardinal Grosbeak (*Cardinalis virginianus*) from North America, a Lazuline Finch (*Guiraca parellina*) from Mexico, presented by Miss E. A. Krumbholz; an Orbicular Horned Lizard (*Phrynosoma orbiculare*) from California, presented by Miss Mabel Baker; a Frilled Lizard (*Chlamydosaurus kingi*) from Roebuck Bay, West Australia, presented by Mr. Saville-Kent; an Orang-outang (*Simia satyrus*, ♀) from Borneo, three Pratincoles (*Glareola pratincola*), European, an Eyed Lizard (*Lacerta ocellata*) from North Africa, a Brazilian Tortoise (*Testudo tabulata*), a Black Tortoise (*Testudo carbonaria*) from Brazil, deposited; two Plumed Ground Doves (*Geophaps plumifera*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

Terrestrial Helium.—The discovery by Messrs. Runge and Paschen of the duplicity of the bright yellow line seen in the spectrum of the gas obtained from cleveite, and of its apparent non-coincidence with the solar D_3 line, as announced in Nature of June 6, has naturally led to the re-observation of the solar line.

Mr. Lockyer informs us that on June 14, observing in the fourth order spectrum of a grating having 14,438 lines to the inch, he found the D_3 line in the chromosphere to have a considerable breadth with rather uncertain indications of doubling, while in the spectrum of a prominence the line was much better defined, and was distinctly double, the less refrangible component being the fainter, as in the case of the gas from cleveite.

Writing under date June 25 (*Ast. Nach* 3302), Prof. G. E. Hale gives a preliminary account of the observations he has made with the powerful spectroscope of the Kenwood Observatory. To eliminate the effect of the sun's rotation in displacing the lines, observations were made of the chromosphere at the sun's north and south poles.

On June 19 and 20 the chromospheric line was found to be 0·54 tenth metres broad, the wave-length of the middle being determined as 5875·924. In the spectrum of each of two prominences observed on June 20 and 21, an inconspicuous bright line was detected on the less refrangible side of D_3, both lines being narrow and sharp, and the distance between them being 0·357 tenth metres. The absence of metallic lines, other than H and K, indicated that the fainter line was probably not due to the accidental proximity to D_3 of a faint metallic line. Further observations on June 24 showed that the broad line in the chromosphere was also divisible into two parts, and it became evident that the wave-length of the D_3 line determined on June 19 and 20, as well as that determined by Rowland, must be affected by an error on account of the presence of the faint line on the less refrangible side. So far, Prof. Hale has not succeeded in obtaining a measure of the wave-length of the more refrangible and brighter of the solar D_3 lines, considered as a separate line.

The results so far obtained may be stated as follows:—

λ of solar D_3 line (Rowland)	5875·982
,, ,, ,, (Hale)	5875·924
,, brightest component of terrestrial line (Runge and Paschen)	5875·883
Distance apart of components of terrestrial line (Runge and Paschen)	0·323
Distance apart of components of solar D_3 (Hale)	0·357

The wave-length of the brighter component of the solar D_3 line remains to be determined before the question of the identity of the solar and terrestrial gas can be regarded as completely set at rest.

The announcement that the yellow line of the gas from cleveite was double, also led Dr. Huggins to observe the chromospheric line. In his first attempts he failed to see the line double (*Chemical News*, No. 1855), but he now states that he clearly saw the line to be double on July 10, 11, and 13, the less refrangible line being the fainter, and the distance apart of the lines being about the same as that of the lines in the cleveite gas according to Runge and Paschen (*Ast. Nach.* 3302).

It is worth recalling that Belopolsky observed the solar D_3 line to be double in May 1894, and ascribed the appearance to the superposition of a telluric line upon the bright line. Prof. Hale's observations demonstrate very clearly that Belopolsky's explanation cannot possibly account for the doubling of the line as observed by him.

Ephemeris for Barnard's Comet, 1884 II.—The following search ephemeris for the return of this comet is due to Dr. Berberich (*Ast. Nach.* 3301):—

	R.A. h.	m.	s.	Decl. °	′
Aug. 2	2	23	9	+ 12	29
6	2	29	7	13	19·5
10	2	34	30	14	6·8
14	2	39	16	14	50·9
18	2	43	23	15	31·9
22	2	46	48	16	9·7

The positions are for Berlin midnight, and are computed on the assumption that the comet will pass through perihelion on June 3. On June 30, Swift discovered a nebulous object in R.A. 20°, decl. + 2° 55′, which was missing on July 4, and was thought to be a possible return of the comet for which the ephemeris is given above. Dr. Berberich states that the observation by Swift does not fit closely into the orbit.

The August Meteors.—Shooting stars from various radiants appear during the month of August: but the most important shower is that of the Perseids. These are visible for a considerable period, with a maximum on August 10. According to Mr. Denning, the radiant point exhibits an easterly motion among the stars; on the 10th it is situated in R.A. 45°, decl. 57° N.; on August 2 it is in R.A. 36°, decl. 55°, and on August 16 in R.A. 53°, decl. + 58°. The density of the shower varies but little from year to year, the number of meteors seen by one observer on the morning of August 11 being from sixty to eighty. Unfortunately the moon rises about nine o'clock on the 10th, so that this year only the brighter meteors will be visible.

THE SUN'S PLACE IN NATURE.[1]

IX.

In most of the earlier attempts which were made to explain the origin of new stars, the leading idea was that of a single body being suddenly disturbed in some way, with the possible result that the heat of its interior became manifested at the surface. Thus Zöllner, in 1865, suggested that the phenomena might be

[1] Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December, 1894. (Continued from page 255).

produced by the bursting of the crust which had just formed on the surface of a star approaching extinction. Again, in connection with the new star in Corona, I pointed out in 1866 that all that seemed necessary to get such an outburst in our own sun was to increase the power of his convection currents, which we know to be ever at work. Dr. Huggins at that time believed that the appearances were due to gaseous eruptions in a single body, and that "possibly chemical actions between the erupted gases and the outer atmosphere of the star may have contributed to its sudden and transient splendour."

Though Zollner's theory was further advocated by Vogel and Lohse in 1877, the idea that such outbursts can be produced in a single body, without external influence, is now almost universally abandoned.

The alternative hypotheses mostly have to do with the possible action between two bodies—an idea first suggested by Newton—and, as I have already pointed out, the evidence that two bodies were engaged in the case of Nova Aurigæ, at least, is conclusive. Even Dr. Huggins has found it necessary to suppose the existence of two bodies, in order to explain the phenomena observed in this case: and Dr. Vogel, who made some most admirable observations during the appearance of this new star, states most distinctly that we can no longer regard the assumption of a single body as sufficient in any explanation of the occurrence.

Notwithstanding the general agreement as to the presence of at least two bodies in the outburst of Nova Aurigæ, there remain considerable differences of opinion as to the nature of the separate bodies, and of the kind of interaction between them.

One explanation which has been suggested ascribes the luminous effects to the development of heat due to the passage of a dark body through a gaseous mass, somewhat after the manner in which meteoric stones produce the appearances of shooting stars in passing through our atmosphere. This kind of action was first suggested by Mr. Monck in 1885, but the possibilities of such actions have been recently more fully discussed by Prof. Seeliger. He points out that the photographic investigations of Dr. Max Wolf and others leave but little doubt that space is filled with more or less extensive aggregations of thinly-scattered matter, which may be called cosmical clouds, thereby accepting my view of a "meteoritic plenum."

If a heavenly body in rapid motion becomes involved in one of these cosmical clouds, its surface will become heated, and the vapourised products will be partly detached and assume the velocity of the cloud; the fluctuations of brilliancy of a new star on this hypothesis are produced by the varying density of the cosmic cloud through which the body is passing.

This hypothesis of Prof. Seeliger's has been strongly combated by Dr. Vogel.

Another explanation depending upon the action of gases has been suggested by Dr. Huggins:

"The phenomena of the new star scarcely permit us to suppose even a partial collision; though if the bodies were very diffuse, or the approach close enough, there may have been possibly some mutual interpenetration and mingling of the rarer gases near their boundaries."

The idea that the phenomena might be produced by the close approach of two bodies, and the consequent disturbances due to tidal action, was first started by Klinkerfues; it has been recently strongly advocated by Dr. Huggins, though I fail to see how it fits in with his previous explanation.

The tidal theory differs from Zollner's only in ascribing the eruptions to the disturbances produced by tidal action when two bodies approach each other. To employ the words used by Dr. Huggins, the tidal action gives rise to "enormous eruptions of the hotter matter from within, immensely greater, but similar in kind, to solar eruptions." This explanation, however, has met with much opposition on physical grounds.

Thus, Prof. Seeliger writes:

"The [illegible] theory of the tides, which is used throughout, is quite incapable of giving a correct representation of the deformations which are doubtless produced by the close passage of the two bodies; for with very eccentric orbits (which it is necessary to assume on other grounds), the continually varying action would last for so short a time that one could scarcely expect to derive a trustworthy conclusion in regard to the actual circumstances from a consideration based on the forms which the bodies could assume in equilibrium."

Again, Vogel [illegible] that:

"Sensible tidal action cannot be assumed to last for any considerable time, as on account of the great relative velocity of the bodies, they would separate at the rate of forty-six millions of miles per day."

These, however, are not the only objections which may be raised to the idea that we have to do with phenomena of the nature of solar prominences, whether produced by tidal action in the case of two bodies, or by a bursting of the crust which is forming in the case of a star approaching the end of its career as a luminous body. In the first place, there is no reason to suppose that the prominences in our own sun are produced by tidal action. The fact that many of the lines seen in the spectrum of Nova Aurigæ during its first appearance were coincident with lines seen in the solar chromosphere, appears, at first sight, to support the idea, but, since the spectra of nebulæ also show chromospheric lines, the same argument might also be applied to prove that nebulæ are manifestations of prominences. I do not imagine that very many will be prepared to believe that nebulæ are prominences, for if they are, they must be prominences of an unseen sun!!

Mr. Maunder and others have pointed out that if the phenomena be due to the formation of solar prominences, the bright lines should be displaced to the more refrangible sides of their normal places, for the reason that only those prominences on the side of the star presented to us would be able to produce visible bright lines, and such prominences would necessarily have their chief movement in a direction towards the earth. We have seen, however, that in Nova Aurigæ, the actual displacement of the bright lines was just the reverse.

Again, the fact that Nova Aurigæ ended by becoming a nebula is difficult to reconcile with the idea that in its earliest stages its luminosity was produced by outbursts of the nature of solar prominences. Nothing seems more remote than the possibility of prominences cooling down and becoming nebulæ. To have so-called "solar prominences" there must be a sun to produce them, and that must remain when the outburst of prominences has ceased; in this case the last stage of the spectrum of the new star should have resembled that of the sun. The fact that it did not indicates how worthless is the prominence suggestion in the light of modern knowledge.

Another very important objection to the solar prominence theory is this: If new stars are real stars capable of exhibiting prominence phenomena, then we have real stars ending as nebulæ, and thus clashing with the idea now accepted even by Dr. Huggins, that nebulæ are "early evolutionary forms" of heavenly bodies. Further, if new stars be real stars, we should have to believe that the last expiring atmospheres of stars consist of hydrogen and unknown gases; but if we take the evidence afforded by the stars themselves, we find that instead of their last atmosphere consisting of hydrogen it indicates carbon or carbon compounds.

It is evident, therefore, that at present there is no agreement among authorities as to which of the special theories I have brought to your notice is to hold the field, each special hypothesis having got no further than a damaging criticism from the authors of the others.

The remaining general hypothesis we have to consider is that advanced by myself. We have everywhere in space, as is now being revealed to us, especially by the photographs of Barnard, Max Wolf, and others, meteoritic aggregations, swarms, and streams, the constituents of which are, comparatively speaking, at rest, or are all moving one way, if they are moving at all, and undisturbed, because they are not being intersected by other streams or swarms at any one time. But supposing any of these bodies cross each other, as unfortunately sometimes excursion trains cross each other, then there is a very considerable difference in the phenomena; there are collisions, and the collisions produce increased light, and we think that a new star is being born. Nothing of the kind. No new star is being born; there is simply a disturbance in a certain part of space, and when the disturbance cools down we shall find that that part of space is still absolutely in the same order. In the case of Nova Aurigæ, and in the case of Nova Cygni after the war was over, nebulæ have been found to lie in the precise positions occupied by the new stars, and the only thing that one has to say about it is that the nebulæ were there before, but that in consequence of our incomplete survey of the heavens they had not been observed.

After the new photographic chart of the heavens has been made, in future times, it will be found that all new stars are not really new, but the lighting up of something which existed there already. The argument for this theory, you will understand, is

simply this. Suppose I light a match, the smaller the match the sooner will it go out, and similarly the larger a fire the longer will it last. So if you are dealing in space with those illuminations which disappear in hours, days, or weeks, you cannot be dealing with any large mass; therefore the collisions in question cannot be between large masses of matter, but it must be a question of collisions amongst the smallest particles of matter we can conceive.

It is interesting to consider one of the possibilities which may explain why small nebulæ may be overlooked in telescopic observations. In the so-called achromatic telescope, all the rays of light are not brought to quite the same focus, so that when ordinary stellar observations are being made, the focus is adjusted for yellow rays which are most luminous to the eye. Now the greater part of the visual light of a planetary nebula is confined to a single line of the spectrum in the green, so that the focus which is best adapted for observations of stars is not suitable for the observation of a small nebula, the nebula being out of focus, and its feeble light thus reduced by the diffusion of the image. This difference is much more marked in large than small telescopes, and Prof. Campbell has pointed out that a small nebula like Nova Aurigæ will in general appear relatively brighter in a small telescope than a large one.

I will next go into some details touching the phenomena of the Novæ in relation to the hypothesis.

First let us see the crucial phenomena we have to explain. We have (1) the sudden bursting out of light and accompanying spectra; (2) the indication of the existence of two bodies revealed by the spectra; (3) the variations and dimming of the light and accompanying spectral changes; and (4) the final stage giving us the spectrum of a nebula.

Since the new era of spectroscopic work has begun, Nova Aurigæ and Nova Normæ have proved to us that the sudden illumination was, to say the least, associated with two bodies, and that these were in different stages of condensation. On the meteoritic hypothesis it was shown that the main differences between bodies giving bright and dark line spectra is one of condensation only: a sparse swarm gives us bright lines because the number of meteorites in unit volume is small and the interspaces are great; a more condensed swarm gives us dark lines because the number of meteorites in unit volume is greater, and the atmospheres of cooler vapour round each meteorite in collision begins to tell because the interspaces are reduced. I am the more justified in insisting upon the importance of this view that two bodies in different stages of condensation are involved, because years after it was formulated Dr. Huggins apparently arrived at it independently—at all events he makes no reference to my prior announcements when he brings it forward as an explanation of the phenomena.

The following quotations will show how this matter stands:—

"If we assume a brightening of the meteor-swarm due to collisions as the cause of the so-called new stars, we have good grounds for supposing that in these bodies the phenomena should be mixed, for the reason that we should have in one part of the swarm a number of collisions probably of close meteorites, while among the outliers the collisions would be few. We shall, in fact, have in one part the conditions represented in Class III*a*, and in the other such a condition as we get in γ Cassiopeiæ."[1]

"The discussion of the observations which have been made of the changes that take place in the spectra of new stars, has already shown that the sequence of phenomena is strikingly similar to that which occurs in cometary spectra after perihelion passage. In general, however, there will be a difference: namely, that in comets there is usually only one swarm to be considered, whereas in new stars, there are two, which may or may not be equally dense. In new stars, we have accordingly the integration of two spectra, and the spectrum we see will depend upon the densities and relative velocities of the two swarms."[2]

"The spectrum of Nova Aurigæ would suggest that a dense swarm is moving towards the earth with a great velocity, and passing through a sparser swarm, which is receding."[3]

"The circumstance that the receding body emitted bright lines, while the one approaching us gave a continuous spectrum with broad absorption lines similar to a white star, may, perhaps, be accounted for by the two bodies being in different evolutionary stages, and consequently differing in diffuseness and temperature."[4]

[1] November, 1887. Lockyer. *Proc.* R.S., vol. xliii. p. 147.
[2] November, 1890. Lockyer. *Phil. Trans.*, 182 A, p. 407.
[3] February 11, 1892. Lockyer. *Proc.* R.S., vol. l. p. 435.
[4] May 16, 1892. Dr. Huggins. *Proc.* R.S., vol. li. p. 494.

Now two sheets or streams of meteorites interpenetrating and thus causing collisions will produce luminosities which will indicate the condensation of each, and the spectra of the two Novæ we are considering thus indicate that the colliding swarms were of different degrees of condensation, and the variations of light observed indicate several such encounters between less dense swarms after the most dense one had somewhat cooled down. The final stage was arrived at and the pure nebula spectrum produced when the most condensed swarm had ceased to indicate any disturbance, after all the others had returned to their pristine quiet and invisibility.

It is important to insist upon the fact that the nebulæ are now almost generally conceded to represent "early evolutionary forms." We have then from the first appearance of a Nova to the last a "backwardation" in the phenomena ending in an "early evolutionary form." Increase of temperature is accompanied by spectral changes in a certain order: if the temperature is reduced the changes occur in reverse order, until finally we reach the "early evolutionary form," which cannot be a mass of gas because its temperature is lower than that of the sun, which it is potentially, and it must contain all the substances eventually to appear in the atmosphere of the sun.

On the hypothesis, then, we imagine a nebula in the position occupied by Nova Aurigæ not chronicled for the reason stated. This nebula is approaching us. It was disturbed by a much sparser stream leaving us, the relative velocity being over 500 miles a second. During the time of impact, the disturbances produced in the two swarms gave rise to bright-line spectra in the sparse swarm, and to dark-line spectra in the more condensed one. The spectrum of the sparse swarm disappears, the spectrum of the dense swarm changes gradually from dark to bright lines, and ultimately it puts on the original nebula spectrum. It is still there, and still approaching us.

We have next to consider the objections which have been urged against this hypothesis. They are of a most trivial nature. An objection made by Vogel is that it is improbable that the velocities could have been so great after collisions. The reply is easy. The light was produced by the disturbed members of the two swarms which escaped end-on collision. On the meteoritic hypothesis we can escape from the difficulties produced by the old idea of collisions *en bloc*. Such objectors would urge that the velocity of a comet as a whole would be retarded by passing through the sun's corona, but we have instances to the contrary.

Another objection has been raised by Dr. Vogel because in relation to the Nova I did not restate all I had previously written concerning the origin of the cause of bright and dark line spectra in stars. It has been difficult for him to understand how one (temporary) star should have bright lines in its spectrum, and another (temporary) star should have dark lines. All I can say is that upon such objectors lies the onus of producing a more simple (and yet sufficient) explanation than that I have suggested.[1]

J. NORMAN LOCKYER.

(*To be continued.*)

THE INTERNATIONAL GEOGRAPHICAL CONGRESS.

THE International Geographical Congress, now a recognised institution, has this year met for the first time on British ground. Originating in a festival organised to celebrate the inauguration of statues of Mercator and Ortelius at Antwerp and Rupelmond, the first Congress was held at Antwerp in August

[1] It has been stated that the meteoritic hypothesis has received a fatal blow from the observations of the Nova (*Astronomy and Astrophysics*, 1892, p. 509). Capable and unprejudiced persons I think will not be of this opinion. I append a quotation from an article by Prof. Campbell, which has appeared since the lectures were delivered.

"As bearing upon any possible theory of Nova Aurigæ, perhaps it will not be out of place to say here what I said last winter in another journal (Pub. A.S P. vi., 52, 133.) The Harvard College Observatory has shown that both Nova Aurigæ and Nova Normæ at discovery possessed substantially identical spectra of bright and dark lines, similarly and equally displaced. Both diminished in brightness, and both assumed the nebular type of spectrum. The new star of 1876 in Cygnus probably had nearly an identical history: passing from a bright star with a spectrum of bright and dark lines, to a faint object with a spectrum consisting of one bright line (undoubtedly the nebular line λ 5010, or the two nebular lines λ 5010 and λ 4960 combined). We may say that only five 'new stars' have been discovered since the application of the spectroscope to astronomical investigations, and that three of these have had substantially identical spectroscopic histories. This is a remarkable fact. We cannot say what the full significance of this fact is. One result, however, is very clear: the *special* theories propounded by various spectroscopists to account for the phenomena observed in Nova Aurigæ must unquestionably give way to the more *general* theories. (*Astrophysical Journal*, Jan. 1895, p. 51.)

1871, under the name of the "Congrès des Sciences géographiques, cosmographiques, et commerciales," and under the influence of the revival of geographical learning subsequent to the Franco-German War, it has met from time to time at different centres, gaining strength and vitality on each occasion. The second Congress assembled at Paris in 1875; the third at Venice in 1881; the fourth at Paris in connection with the Great Exhibition of 1889; and the fifth at Berne in 1891. In each case the representative Geographical Society of the country concerned was responsible for the organisation and arrangement of the meeting, and at Berne it was definitely resolved that in future the Congress should be constituted at intervals of not less than three, nor more than five years, the resolution taking practical shape in the acceptance by the Royal Geographical Society of the responsibilities of a meeting in London in 1895. A proposal, emanating from the Berne Geographical Society, to the effect that the chief officials of each Congress shall retain office until the meeting of the next, is to be submitted this year, and its acceptance would mark a further step towards the establishment of a great permanent organisation for the systematic study and exploration of the globe.

The sixth Congress differs from its predecessors in a characteristically British fashion, inasmuch as it is practically a private enterprise; no State or municipal aid being forthcoming, as on previous occasions. Nevertheless the Royal Geographical Society, aided by grants from a few of the City companies and by private generosity, has been able fully to cope with the demands made on its resources by the immense influx of geographers from all parts of the world. Accommodation has been found in the Imperial Institute, which affords ample room for private and public business meetings, for exhibitions, and for all manner of social functions, as well as opportunity for that private intercourse which goes so far to enhance the value of such meetings. The Congress is under the patronage of the Queen and the Prince of Wales, and the honorary presidency of the King of the Belgians, the Duke of Connaught, the Duke of York, the Crown Prince of Denmark, and the Grand Duke Nicolas Michailovich. The President is, according to the custom of the Congress, the President of the Geographical Society under whose auspices it meets: in this case the President of the Royal Geographical Society, Mr. Clements R. Markham, C.B., F.R.S. A large number of eminent public men and geographers have accepted the position of honorary vice-presidents.

The work of organisation has been carried out by a number of committees, under the chairmanship of Major L. Darwin, R.E.: the general secretaryship is in the hands of Mr. J. Scott Keltie and Dr. H. R. Mill; and the exhibition is under the direction of Mr. E. G. Ravenstein, Mr. John Coles, and Mr. John Thomson.

In devising the general arrangements, it has hitherto been the practice to abstain from formulating any rigorous rules, and to leave the managing Society a pretty free hand. In some cases, notably at Venice, the Congress was somewhat overwhelmed by the exhibition of geographical objects; while in others undue subdivision into sections has tended to defeat one of the most praiseworthy objects of the meeting. Profiting by the experience obtained, the Royal Geographical Society has kept the range of the exhibition within comparatively narrow limits. The Geographical Societies of Paris, Berlin, and St. Petersburg, and various Government departments and private individuals in all parts of the globe have sent representative exhibits of recent work, and the collections have been in many cases arranged entirely by the exhibitors. Another department is devoted to paintings and photographs of geographical interest, including, amongst other things, a series of historical portraits of eminent travellers, cartographers, and geographical writers, many valuable sketches and photographs contributed by explorers, and lantern slides and diagrams adapted to the purposes of geographical education. A third section, due to Mr. E. G. Ravenstein, consists of a loan exhibition, intended to illustrate the development of cartography from the time of Ptolemy to the end of the eighteenth century. Mr. Ravenstein is to be congratulated on the achievement of a remarkable success, for while no important stage of progress is unrepresented, those illustrated by facsimiles only are wonderfully few. The collection includes many priceless examples, such as the Leonardo da Vinci maps belonging to the Queen, the "Henry II." map belonging to the Earl of Crawford and Balcarres, the Mollineux globe from the library of the Middle Temple, the Agas map of London from the Guildhall, the manuscripts of the early Indian surveys by Pitcher and Rennel, Topping, Maclure, and Mackenzie, from the India Office, and extensive contributions from the libraries at Lambeth Palace, the Admiralty, the Ordnance Survey, various Geographical Societies, and the private collections of Mr. S. W. Silver, Mr. H. Yates Thompson, Mr. E. A. Petherick, and many others. It is to be noted that the catalogue of this exhibition, with its appended list of maps, portolani, and atlases in the British Museum, forms an excellent bibliographical outline of the subject.

A similar collection, though on a necessarily smaller scale, has been made by Mr. John Coles, in the department of surveying and meteorological instruments. The exhibits of the Hydrographic Department of the Admiralty and the Ordnance Survey Office are of great historical interest. We could have wished it had been possible to allot a further space to instruments used in deep sea explorations, especially as their modern developments are so well illustrated by Prof. Otto Pettersson and Dr. H. R. Mill.

A final section of the exhibition consists of the most recent equipments for exploration, surveying, mapping, and teaching geography, shown by numerous private firms.

The same leading idea, that of representing general features, has been kept in view in arranging the work of the meetings. While no attempt has been made to present popular programmes, the whole range of geography has been covered, and the chief effort directed towards furthering those larger interests which concern all geographers, rather than to the discussion of more minute technicalities, however important in themselves. Thus general meetings are to be devoted to Polar Exploration, the development of Africa, Exploration, and Cartography; and sectional meetings deal with Geographical Education, Photographic Surveying, Physical Geography, Geodesy, Oceanography, Geographical Orthography and Definitions, and Limnology.

The date of our going to press constrains us to defer a report of most of the work done in all these different departments until next week, except in so far as the earlier meetings are concerned. On Friday evening (July 26) the delegates were presented to H.R.H. the Duke of York by the Ambassador or Chargé d'Affaires of their respective countries. The following were represented, either by Government delegates or by delegates of Geographical Societies:—Austria-Hungary, Belgium, Denmark, France, Germany, Greece, Italy, Netherlands, Norway, Portugal, Roumania, Russia, Spain, Sweden, Switzerland, Turkey, United States, Mexico, Brazil, Japan, Persia, New South Wales, New Zealand, Queensland, South Australia, Tasmania, Victoria, Western Australia, Cape of Good Hope, and the United Kingdom. After the private reception, the Duke of York welcomed the whole Congress in the name of the Queen and the Prince of Wales, and the President made a brief address of welcome on behalf of the Royal Geographical Society, the other British Geographical Societies, and the Geographers of the United Kingdom. The Hon. Chief Justice Daly, of the New York Geographical Society, the oldest President of a Geographical Society living, replied on behalf of the foreign members and delegates, and the meeting adjourned, the remainder of the evening being spent in the gardens of the Institute, where music was discoursed by Strauss' orchestra.

On Saturday (July 27) the Congress assembled at 10 a.m. to hear the President's opening address, which paid a graceful tribute to the geographical work of the nations whose delegates and representatives he cordially welcomed, and gave a forecast of the work about to be undertaken by the Congress. A vote of thanks was proposed by Prince Roland Bonaparte, and seconded by Prof. von den Steinen. At noon two sections were formed. In Section B, which was presided over by Mr. Markham, supported by Chief Justice Daly and Prof. von den Steinen, Prof. Levasseur read a paper on geography in schools and universities, which outlined a system of geographical education extending through primary, secondary, and higher stages. Señor Torres Campos supported the views expressed by Prof. Levasseur, and discussion was continued by M. Ludovic Drapeyron. The importance of a university training for teachers of geography was urged by Dr. R. Lehmann in the second paper, and the needs of geography in secondary education were set forth by Mr. A. J. Herbertson in the third. Thereafter Dr. W. Henkel allowed a paper on geography and history in schools, standing in his name, to be held as read, in order to allow time for discussion. Mr. H. J. Mackinder advocated the establishment of a central school of geography in London, in order to place geographical teaching in this country on a proper footing. Mr.

G. N. Hooper referred to the work done by the London Chamber of Commerce, and the discussion was continued by Messrs. Phillips, Burgess, Batalha Reis, and Yule Oldham. The President proposed that a committee, consisting of Chief Justice Daly (chairman), Prof. Levasseur, Prof. Lehmann, Mr. Mackinder, and Mr. Herbertson, should be appointed to consider a resolution on geographical education, to be submitted to the Congress.

Section C, which met at the same time, concerned itself with photographic surveying. The presidential chair was occupied by Prince Roland Bonaparte and General Walker jointly. In a paper read on his behalf by M. Schrader, Colonel Laussedat considered the application of photography to the rapid determination of points in levelling, and a combined camera and theodolite was exhibited. M. de Déchy, in discussion, insisted that photography must always be merely auxiliary to triangulation, and must not in any way replace it; and Mr. Coles described his work in constructing a map of the Caucasus from photographs alone. Captain E. H. Hills then read a paper on the determination of terrestrial longitudes by means of photography, in which he described improved methods of exposing and measuring plates used in photographing lunar distances, by means of which he had obtained better results than those obtained by Schlichter and Runge. An abstract of a paper by Prof. J. Thoulet, suggesting the extended application of photography to the survey of rapidly shifting sandbanks, was read in his absence. Mr. Coles described and exhibited Colonel Stewart's camera for producing photographs of the whole horizon, and the proceedings closed with an informal communication by M. Janet on the determination of longitudes without instruments of precision.

HELIUM, A CONSTITUENT OF CERTAIN MINERALS.[1]

II.

(II.) *The Properties of Helium.*

FROM what has preceded, it appears that up to now only three minerals are available as sources of helium, unless, indeed, very large quantities of samarskite and yttrotantalite are worked up. These three are clèveite, the uraninite investigated by Hillebrand, and bröggerite. And here we wish to express our indebtedness to Prof. Brögger for his great kindness in placing a large stock of bröggerite at our disposal. It has furnished a large quantity of the helium which we have had in our hands.

Although, so far as we were able to judge by throwing into a two-prism spectroscope of Browning's the spectra of samples of gases obtained from the minerals previously mentioned, all the specimens of helium were identical, still a further proof was desirable. Owing to the small quantities of gas yielded by these minerals, amounting in most cases to a few c.c., it was impossible to ascertain whether these samples were of the same density; but the case was different with the gas from clèveite and from bröggerite. In each case a sufficient quantity was obtained to make it possible to determine the density with fair accuracy. It will be convenient therefore to describe the methods of extracting the gas and the methods determining its density.

In the communication to the Royal Society it was stated that the maximum density of the original gas from cleveite was 3·89. The spectroscope showed the presence of nitrogen in this sample; the bands were very brilliant at high pressure, but on reducing the pressure the yellow line became brilliant, and the nitrogen spectrum disappeared. This always happens when the tube has platinum electrodes and a strong discharge is passed for a considerable time. An attempt was made to remove the nitrogen from this sample of gas by circulating it over red-hot magnesium; but an unfortunate accident caused the admixture of about its own volume of air, carrying with it argon, from which at present there is no known method of separating helium.

It appeared important to decide whether the gas evolved from these minerals is helium, or a compound of hydrogen and helium; for in the preliminary set of experiments the treatment was such that a hydride would have been decomposed either by sparking with oxygen or by passage over copper oxide at a red heat.

[1] A paper by Prof. William Ramsay, F.R.S., Dr. J. Norman Collie, and Mr. Morris Travers, read before the Chemical Society on June 20. (Continued from p. 308.)

The result of experiments directed to this end is to show that no combined hydrogen is present. Gas was extracted from nineteen grams of bröggerite by heating it in a combustion-tube to dull redness; the combustion-tube was connected with a Töppler's pump by means of thick-walled india-rubber tubing, wired carefully. Special experiments showed that the leakage through the india-rubber amounted between Saturday and Monday to less than one small bubble. The bröggerite yielded about 75 c.c. of gas, a large portion of which was absorbed by caustic soda, leaving about 35 c.c. A second charge of 18·3 grams gave 58·5 c.c., and a third, of 22·1 grams, gave 66·0 c.c. The amount of gas evolved depends largely on the temperature. The evolution is rapid at first, but becomes very slow after three hours, and the heating was always stopped before all the gas which might have been extracted had come off. The last portions, as will be seen later, were extracted by fusion with hydrogen potassium sulphate.

This crude product from bröggerite blackened mercury, doubtless owing to the presence of hydrogen sulphide.

The density of this sample was determined: the data are these.

Volume of bulb	33·023 c.c.
Temperarure	22·9
Pressure (corr.)	766·7 mm.
Weight...	0·0327 gram
Density (O = 16)	11·90

The exceedingly small capacity of the bulb calls for some remark, but for no apology. The object here is, not to determine the density with the utmost accuracy, but to secure a guide, sufficient for our purpose, which will indicate the probable molecular weight. Now the hydrogen contained in such a bulb at 0° and 760 mm. weighs approximately 0·0030 gram. A sensitive balance by Oertling, adjusted for the special purpose, could easily be read to 0·00005 gram, without resorting to the the reading of oscillations of the pointer; and this gives an accuracy of 5 parts in 300, or 1·7 per cent. Hence the density of hydrogen, thus determined, might vary between 0·983 and 1·017. It is evident that such an approximation is quite sufficient for our present purpose. The total volume of this gas was 124·5 c.c. A solution of soda was introduced by means of a pipette, and after all absorption had ceased, the residue measured 78·0 c.c. The density was again determined.

Volume of bulb	33·023 c.c.
Temperature	21·6°
Pressure (corr.)	765·4 mm.
Weight	0·0058 gram
Density (O = 16)	2·105

This gas was now left in contact with palladium sponge for a night. The sponge was made by reducing the chloride in a current of hydrogen, at a dull red heat. As it was somewhat porous, it was hammered on a steel anvil before introducing it into the gas, which, of course, was confined over mercury. The contraction amounted to abont 1/30th. The density was again taken.

Volume of bulb	33·023 c.c.
Temperature	19·2°
Pressure (corr.)	760·2 mm.
Weight	0·00630 gram
Density (O = 16)	2·284

This gas had undergone no treatment which was of a kind to remove combined hydrogen, unless, indeed a very improbable assumption—it be supposed that the compound should be decomposed by contact with metallic palladium. The gas was therefore placed in contact with copper oxide, which had previously been heated to redness in a vacuum, and a tube filled with phosphoric anhydride was so interposed as to absorb any water produced. The gain in weight of this tube was 0·0016 gram, indicating the oxidation of about 2 c.c. of hydrogen. In all probability this hydrogen had remained over after treatment with palladium; for it bears no proportion to the total quantity of gas—78 c.c.

The density was again determined.

Volume of bulb	33·023 c.c.
Temperature	16·67°
Pressure (corr.)	754·9 mm.
Weight	0·00720 gram
Density (O = 16)	2·606

We give thus minutely all the determination of density of such samples, because, although they refer to an imperfectly purified sample, yet they show that the density is very low, and they trace, moreover, the gradual change as one ingredient after another is removed.

The bröggerite which had been heated in a vacuum was next fused in successive portions with hydrogen potassium sulphate. A large quantity of gas was evolved, consisting of sulphur dioxide, carbon dioxide, nitrogen, and helium. The sulphur dioxide was removed with chromic mixture, and the carbon dioxide with caustic soda: the yield was 45 c.c. The density was then determined.

Volume of bulb	33·023 c.c.
Temperature	16·18°
Pressure (corr.)	753·3 mm.
Weight	0·01035 gram
Density (O = 16)	3·748

No alteration in volume occurred on passing the gas for several hours over red-hot copper oxide. Hence no hydrogen was present in the free state; and if combined, passage over copper oxide does not decompose the hydride, as was seen before, when the water produced was weighed. It may be remarked that every known hydride would yield its hydrogen on such treatment.

This sample of gas was next circulated over red-hot magnesium for several hours. It is hardly necessary to state that the magnesium was first heated to redness in a vacuum so as to remove hydrogen. In case any should escape removal, however, a red-hot tube of copper oxide formed part of the circuit, as well as a tube filled with phosphoric anhydride. Some caustic soda solution was present in the reservoir above the mercury, which would have absorbed the products of combustion of any hydrocarbon present. The density of this gas was calculated from the data appended.

Volume of bulb	33·023 c.c.
Temperature	14·88
Pressure (corr.)	756·0 mm.
Weight	0·00845 gram
Density (O = 16)	3·037

On examining the magnesium tube, after it had cooled, it was found that on moistening it ammonia was evolved. The gas was, therefore, again circulated over magnesium, at a somewhat higher temperature, so high, indeed, that the gas must have passed repeatedly through magnesium vapour. On pumping out the tubes, an accident led to the loss of a few c.c. of gas; hence the weighing bulb had to be filled at a somewhat reduced pressure. The density is given below.

Volume of bulb	33·023 c.c.
Temperature	18·33
Pressure (corr.)	615·8 mm.
Weight	0·0049 gram
Density (O = 16)	2·187

Again, on moistening the broken magnesium tube, ammonia was evolved; it was recognised by its odour and by its turning red litmus paper blue.

A further experiment was made with bröggerite. 30·8 grams were heated in a vacuum and the gas was collected over mercury, on to the surface of which a few c.c. of caustic soda solution were introduced. The yield of gas was 65 c.c. It was circulated over copper oxide to remove hydrogen, and its density was then determined.

Volume of bulb	33·023 c.c.
Temperature	19·70
Pressure (corr.)	756·7 mm.
Weight	0·0068 gram
Density	2·481

The density of this sample is almost coincident with that of a previous sample, [illegible], obtained in the same way, after it had been purified from hydrogen. This gas was next circulated over very hot magnesium, so as to remove nitrogen. Again, it is certain that for many hours the gas must have been mixed with magnesium vapour, for the magnesium had been completely volatilised out of the hot part of the combustion-tube, and had condensed at the cool end. Again, the product, when moistened showed the reactions of ammonia, proving that nitrogen had been removed. The density of this sample was next taken.

Volume of bulb	33·023 cc.
Temperature	19·17
Pressure (corr.)	756·7 mm.
Weight	0·0056 gram
Density	2·044

The copper oxide tube was omitted during this circulation; hence the density was low, 2·044. The spectrum of this gas showed hydrogen lines and feeble nitrogen bands. A second determination of density, in which the bulb was freshly filled, gave, at the same pressure and at a temperature differing by only 1 from the previous one, an identical weight. Further circulation for a whole day over red-hot magnesium, raised to the highest temperature which the tube could stand, gave a specimen from which hydrogen and nitrogen were absent: at least, the barest trace was visible in a vacuum-tube filled at a fairly high pressure; and care was taken to interpose a red-hot copper oxide tube, and, as usual, a tube containing phosphorus pentoxide. The effect of this circulation was to raise the density.

Volume of bulb	33·023 c.c.
Temperature	17·1
Pressure (corr.)	763·2 mm.
Weight	0·0060 gram
Density (O = 16)	2·152

It is of interest to note that this sample, procured by heating bröggerite in a vacuum, has a density practically identical with that of gas obtained by fusing bröggerite with hydrogen potassium sulphate: that sample had density 2·187.

We next proceeded to extract the gas from 6·96 grams of Swedish clèveite. When heated in a vacuum, the gas was rapidly evolved at first, more quickly than from bröggerite. About 60 c.c. were obtained, and, after treatment with soda, the residue occupied 26·3 c.c. As this was not sufficient for our purpose, and as we had already by density and spectrum proved the identity of gas evolved from bröggerite on heating, and on fusion with acid sulphate, the remaining clèveite was mixed with about five times its weight of fused and dried hydrogen potassium sulphate, placed in a tube, and heated in a vacuum. A further quantity of gas was evolved, which was at once treated with caustic soda solution. Both quantities of gas were mixed. This sample was then circulated over copper oxide for several hours, and the density was then determined with the following result.

Volume of bulb	33·023 c.c.
Temperature..	19·43°
Pressure (corr.)	763·2 mm.
Weight	0·0061 gram
Density	2·205

The spectrum of this gas showed the merest trace of nitrogen, but no hydrogen. The density, it will be seen, is practically coincident with that of the gas from bröggerite. It is noteworthy that the gas from clèveite contains no nitrogen. We are absolutely certain that the presence of nitrogen in the gas from bröggerite is not to be explained by leakage of air, for the tightness of the apparatus was frequently tested during each operation.

We have therefore three determinations of density, and the mean may be taken as approximately correct to within 0·05. They are:

Gas from bröggerite by heating	2·152
Gas from bröggerite with $HKSO_4$ ...	2·187
Gas from clèveite	2·205
Mean	2·181

All these samples of gas were now mixed and passed through the usual absorbents for nitrogen and for hydrogen, namely magnesium, copper oxide, soda-lime, and phosphoric anhydride. The density of this sample was then determined with the larger bulb. The error due to error in weighing cannot in this case amount to more than 0·3 per cent., and is probably less. Of course, the purity of the gas would affect the result. The data are as follows.

Volume of bulb	162·843 c.c.
Temperature...	17·07°
Pressure (corr.)	704·9 mm.
Weight	0·03057 gram
Density (O = 16)	2·218

The wave-length of sound was determined with this sample of gas in a tube 1 metre in length and 9 mm. internal diameter; the vibrating rod was 580 mm. long. We found it exceedingly difficult to procure a tube in which really good sound-waves could be shown with helium; indeed, we were on several occasions nearly despairing of gaining our object. But at last perfect waves, easily read and easily counted, were produced, and measurements were taken with the following results.

Series	I.	II.	III.	IV.	V.	VI.	VII.
Half wave-length	98·6	98·6	97·6	98·3	100·0	98·6	97·9 mm.

Mean of all, 98·8 mm. at 18·9.

In air, a similar series gave the numbers

Series	I.	II.	III.	IV.	V.
Half wave-length	36·00	36·03	36·11	35·89	36·16

Mean, 36·04 mm. at 20·1°

The ratio of the specific heat at constant volume to that at constant pressure for air is 1·408; that for helium is—

$$\frac{(36{\cdot}04)^2 \times (273 + 18{\cdot}9)}{273 + 20{\cdot}1} \times 14{\cdot}479 : (98{\cdot}8)^2 \times 2{\cdot}218 :: 1{\cdot}408 : 1{\cdot}632$$

This sample of gas was again circulated over very hot magnesium and copper oxide for seven hours; the magnesium had no smell of ammonia when breathed on, nor did it turn red litmus paper blue until after long standing. The magnesium was mostly volatilised out of the hot part of the tube.

The *density* of this sample of gas was determined.

Volume of bulb	162·843 c.c.
Temperature	19·8°
Pressure (corr.)	730·0 mm.
Weight	0·0278 gram
Density	2·133

The wave-length of sound was re-determined in the same tube as before. The figures are

Series	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Half wave-length.	102·7	100·7	101·6	100·7	102·6	101·6	100·9	101·1 mm.

Mean of all, 101·5 mm.

The ratio of the specific heats of helium, calculated from these numbers as before, is 1·652, a sufficiently close approximation to the theoretical number 1·66. In the case of argon, the purest specimen obtained gave for the ratio 1·659; and as remarked (in the *Philosophical Transactions*, 1895, 52), not much dependence can be placed on the accuracy of the last figure.

The result of these experiments goes to prove that the density of the gas named helium is not less than 2·13, and that it has the same claim to be considered a monatomic gas as mercury gas; or if it is a mixture, it must be a mixture of monatomic gases.

As hydrogen was often evolved along with helium from minerals, it occurred to us that if a definite ratio could be found between the helium and the hydrogen evolved by the action of acid, some idea might be gained as to the valency of helium. It would be as if, for example, hydrogen and chlorine were evolved separately from salt by sulphuric acid, instead of in combination; by measuring each, the deduction could be drawn that chlorine was univalent. Experiments made to this end showed, however, that from some minerals no hydrogen is evolved. Gas, from a sample of uraninite sent by Dr. Hillebrand, contained no trace of hydrogen. It is, of course, possible, and, indeed, not unlikely, that all hydrogen is absorbed in reducing the uranic oxide to uranous oxide. The problem then becomes a complicated one; but we hope to solve it by future experiments.

As yet but few experiments have been made with the object of inducing helium to enter into combination. Like argon, it is not attacked by oxygen in presence of caustic soda under the action of the electric discharge; indeed, this forms a good method of removing all impurities other than argon. Again, like argon, it is not affected by red-hot magnesium, and it is not oxidised by copper oxide at a red heat.

As helium is evolved from clèveite and similar minerals at a red heat, an attempt was made to reabsorb it by heating the powdered mineral to redness in contact with the gas, but not to so high a temperature as that which had served to cause it to be evolved. But the attempt was fruitless: no gas was absorbed. When all the gas in the tubes had been pumped out, after they were cold, heating failed to cause the evolution of more gas.

A further experiment was made, in which metallic uranium was heated to bright redness with a blow-pipe in contact with a mixture of helium and oxygen, the latter gas being greatly in excess. But, curiously, the oxidation of the uranium was very slow, and all the helium was recovered, none having been absorbed. The conditions have yet to be discovered under which helium can be made to combine with oxides of uranium, so as to reproduce the natural product.

The Solubility of Helium.

Helium is very sparingly soluble in water. A determination made by the method previously described for argon (*Phil. Trans.* A. 1895, 37) gave 0·0073 as its coefficient at 18·2. The tube contained 162·3 arbitrary divisions, of which 26·0 were occupied by helium and 136·3 by water. After shaking, the volume of the helium was reduced to 25·0 divisions, and that of the water was increased to 137·3. As 137·3 absorb 1·0, 1 volume of water absorbs 0·0073 volume. The whole apparatus was jacketed with running water during this experiment.

This is the lowest solubility hitherto recorded. Generally speaking, the solubility of a gas is related to the temperature at which it condenses to a liquid, and the sparing solubility of helium points to its having a very low boiling point. Prof. Olszewski has kindly undertaken to make experiments on the temperature of liquefaction of helium, and it will be interesting to find whether its boiling point does not lie below, or, at least, as low as that of hydrogen; for their molecular weights are not very different, and helium is a monatomic gas, a condition which appears to lower the boiling point.

Helium is totally insoluble in absolute alcohol and in benzene.

The Spectrum of Helium.

Mr. Crookes is making an exhaustive study of the spectrum of helium, and will shortly publish an account of his work. But, as some of the deductions to be drawn later depend on the lines observed, it is necessary here to add a few words. In general terms, the spectrum has already been described. The particular point to which attention is necessary here is that at least two of the lines in the spectrum of helium, seen with a wide dispersion prism, are coincident with two of the argon lines. These occur in the red, and comprise one of each of the two pairs of characteristic argon lines. This observation has been frequently repeated, using for the purpose spectroscopes of different dispersive power, and throwing into the field both spectra at the same time, with an exceedingly narrow slit: and we may say that if not absolutely identical, the lines are so near that it is not possible with the means at our disposal to recognise any difference in position. But the relative brilliancy is by no means the same. One of the argon lines, rather faint, is coincident with the prominent red of the helium spectrum, and one of the strong red argon lines is coincident with a faint red line in the helium spectrum.

Besides these two, there is a line in the orange-red, which though perhaps not identical, yet is very close. This line is faint in helium, but moderately strong in argon. It is much more easily visible with helium in the "negative glow" than in the capillary tube.

It may also be of interest to state that, according to Runge's observation, the brilliant yellow line of helium is undoubtedly a doublet. This was frequently observed by us with a grating of 14,000 lines to the inch in the spectrum of the third order. But it must also be noted that one of the lines is very faint; the other, more refrangible, is immensely brighter. The distance, judged by eye, appears to be about 1/50th part of that between the lines D_1 and D_2 of sodium. Accurate information on this last point may be looked for from Mr. Crookes, Mr. Lockyer, and from many others who are interested in the probable occurrence of this element in the sun.[1]

III. *General Conclusions.*

It cannot be doubted that a close analogy exists between argon and helium. Both resist sparking with oxygen in presence of caustic soda; both are unattacked by red-hot magnesium; and if we draw the usual inference from the ratio

[1] Prof. Hale and Dr. Huggins have recently observed that the solar line D_3 is also a doublet. (W. R., July 20).

between their specific heats at constant volume and at constant pressure, both are monatomic gases. These properties undoubtedly place them in the same chemical class, and differentiate them from all known elements.

Although opinion is divided on the precise significance of the ratio of specific heats, 1·66, it appears to be most probable that in all cases, as in that of mercury, this ratio points to the monatomicity of the molecule. If we assume this provisionally, it follows that the atomic weight of helium is identical with its molecular weight. The molecular weight is twice the density, for the molecular weights of gases are compared with the atomic weight of hydrogen, taken as unity: hence the atomic weight of helium on this assumption is $2·13 \times 2 = 4·26$. But again we assume, in making this calculation, that helium is a single element, and not a mixture of elements. Before discussing this question, it appears advisable to inquire whether there is any evidence which would corroborate the deduction that it is a monatomic element. This evidence must be sought for in the properties of argon, for those of helium have not as yet been sufficiently investigated.

We know from countless examples among compounds of hydrogen and carbon that increase in molecular weight is accompanied by rise of boiling point; and it may be stated as a proved fact that a polymeride has always a higher boiling point than the simpler molecule of which the polymeride is formed. Among the substances germain to this inquiry, ozone and oxygen may be cited; the complex molecule of ozone is shown by the higher temperature at which it boils. It might be concluded with certainty, therefore, that A_2, could it exist, should have a higher boiling point than A_1.

Next, it is generally the case that the boiling point of an element, provided it has not a complex molecule like that of sulphur and phosphorus, is lower, the lower its molecular weight. There are the well-known instances of chlorine, bromine, and iodine; but if it be objected that these all belong to the same group, we may cite the cases of hydrogen, $-243.5°$; nitrogen, $-194.4°$; and oxygen, $-182·7°$; and we may add chlorine, $-102°$. If argon possessed the atomic weight 20 and the molecular weight 40, it is probable that its boiling point would lie above that of chlorine, instead of, as is actually the fact, at $-187°$—below that of oxygen. But, it may be objected, the boiling point is determined, not by the molecular weight, but by the density. It may be urged that the density of argon is 20, and that its molecules, like those of oxygen and nitrogen, are diatomic, in spite of the argument to the contrary from the ratio of specific heats. The answer to this objection is obvious: if this were so, its boiling point should lie above, and not below that of oxygen.

These considerations cannot, of course, be accepted as evidence, but merely as corroborative of the conclusion as regards the monatomicity of argon. If they apply to argon, they apply with equal force to helium; and if they are accepted, it follows that the atomic weight of helium is 4·26.

It is again necessary to consider the character of argon in attempting to answer the next question: Are argon and helium single elements or mixtures of elements? But before discussing it, let us consider another question: How does argon happen to occur in the air and helium only in minerals? Why is helium not present in air? A satisfactory answer to this question is, we think, contained in a paper by Dr. Johnstone Stoney (*Chem. News*, 1895, lxxi. 67). He there shows that were hydrogen to be present in air (and it might be present, in spite of the oxygen with which it could be mixed, for a small quantity would surely escape combination), it would, in virtue of the velocity of its own proper molecular motion, remove itself from our planet, and emigrate to a celestial body possessing sufficient gravitational attraction to hold it fast. Dr. Stoney suggests this explanation to account for the absence of an atmosphere and of water vapour on the moon, and for the presence of an atmosphere of hydrogen on the sun. It would also account for the absence of helium in our atmosphere, and for the presence of the chromospheric line D_3. Of course, if an element can form compounds, or if it is [illegible], as helium appears to be, it will, like [illegible], be found on the earth.

The inertness of these gases would favour their existence in the free state. Yet argon exists in the atmosphere, precisely because it forms no compounds. Similarly nitrogen is a constituent of air, because in the first place those elements with which it combines directly are comparatively rare, and also because such compounds are mostly decomposed by water; and the excess of nitrogen therefore occurs in the free state. Similarly, the occurrence of free oxygen is due to the fact that some remains over, after all or almost all the readily oxidised substances have already united with oxygen. If there exist gases similar to argon in inertness, they too may be looked for in air.

Now if argon possess the atomic weight 40, there is no place for it in the periodic table of the elements. And up to now there is no exception to this orderly arrangement, if the doubtful case of tellurium be excluded. Rayleigh and Ramsay have shown that the high density of argon can hardly be accounted for by supposing that molecules of A_2 are mixed with molecules of A_1; and excluding as untenable the supposition that argon is a compound, the only remaining suggestion is that it is a mixture. No attempts have as yet been made to test the correctness of this idea; but experiments have already been started which, it is hoped, will throw light on this question.

The density of argon is too high; to fill its place in the periodic table, between chlorine and potassium, its density should be about 19 and its atomic weight 38. We might expect the presence of another element with a density of 41 and an atomic weight of 82, to follow bromine, as argon follows chlorine; and this element would probably also be a gas, since its density would be only a little higher than that of chlorine.

But here we meet with a difficulty. There are certain lines in the spectrum of helium coincident with lines in the argon spectrum. There can be only one explanation, excluding the extremely improbable hypothesis, which is not verified in any instance, that two elements may give spectra containing identical lines. That explanation is, of course, that each contains some common ingredient; and there appears to be a place for one with density 10 and atomic weight 20, to follow fluorine in the periodic table. The density of helium is, however, so low, that there does not appear room for any large quantity of a heavier gas; and to fit the periodic table, the density of argon should be diminished by removal of a heavier admixture, rather than increased by removal of a lighter one.

Such are the problems which now confront us. Until more experiments have thrown further light on the subject, we regard it as labour lost to discuss the relations of these curious elements to others which find their proper place in the periodic table.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SIR JULIAN GOLDSMID has been elected Vice-Chancellor of the University of London, in succession to Sir James Paget, who has resigned.

THE new *Directory* of the Department of Science and Art, which has just come to hand, contains the regulations for Organised Science Schools, previously referred to in these columns. Among other matter new to the *Directory*, and announcements of changes, we notice that a new method of according the National Scholarships is in contemplation. The change will not take effect until the Session 1896–97, and due intimation of its nature will be given. The syllabus of Practical Plane and Solid Geometry has been recast in the elementary stage, in the direction already noted, and new syllabuses are given for Inorganic Chemistry, theoretical and practical, Geology, and Physiography. It is not clear, however, whether the questions to be set for the examinations next May will be based upon the new or the old syllabuses.

AT the ordinary quarterly meeting of the Royal College of Physicians of London, held on Thursday last, Sir Russell Reynolds, F.R.S., in the chair, the following gentlemen were elected officers of the College:—Censors, Sir William H. Broadbent, Dr. P. H. Pye Smith, Dr. T. Tillyer Whipham, Dr. William Cayley; treasurer, Sir Dyce Duckworth; emeritus registrar, Sir Henry Pitman; registrar, Dr. Edward Liveing; librarian, Dr. William Munk; examiners chemistry and chemical physics, Mr. Charles L. Groves, F.R.S., Mr. W. R. Dunstan, Mr. J. Millar Thomson, Dr. Samuel Rideal, Dr. R. Taylor Plimpton; materia medica and pharmacy, Dr. T. Lauder Brunton, F.R.S., Dr. Daniel J. Leech, Dr. Sidney P. Phillips, Dr. Frederick Willcocks, Dr. Francis G. Penrose;

elementary biology, Mr. F. Gymer Parsons, Mr. P. Chalmers Mitchell; elementary physiology, Dr. H. Lewis Jones; physiology, Dr. Vincent D. Harris, Dr. Thomas Oliver, Dr. Frederick W. Mott; anatomy, Mr. Charles Stonham, Prof. G. Dancer Thane; medical anatomy and principles and practice of medicine, Dr. Philip J. Hensley, Dr. J. Burney Yeo, Dr. G. Vivian Poore, Dr. J. Mitchell Bruce, Dr. Frederick Taylor, Dr. Stephen Mackenzie, Dr. William Ewart, Dr. Seymour J. Sharkey, Dr. J. Kingston Fowler, Dr. Robert Saundby; midwifery, Dr. J. Baptiste Potter, Dr. J. Watt Black, Dr. Peter Horrocks, Dr. Walter S. A. Griffith; surgical anatomy and principles and practice of surgery, Mr. John Langton, Mr. J. N. C. Davies-Colley; public health, Dr. Charles H. Ralfe, Dr. William Pasteur; Murchison Scholarship, Dr. F. Charlwood Turner, Dr. Samuel H. West.

WE gave last week the names of the Research Scholars appointed for 1895, by Her Majesty's Commissioners for the Exhibition of 1851. We are now informed that the following scholars, appointed in 1894, have forwarded satisfactory reports of their work during the first year of their scholarships, which have accordingly been renewed for a second year.

Name of Scholar.	Nominating Institution.	Place of Study.
J. C. Beattie	University of Edinburgh	University of Vienna.
J. R. E. Murray	University of Glasgow ...	University of Glasgow.
W. B. Davidson ...	University of Aberdeen...	University of Würzburg.
R. C. Clinker... .	University College, Bristol	University College, Bristol.
F. Dent . .	Yorkshire College, Leeds	University of Munich.
A. J. Ewart	University College, Liverpool ...	University of Leipzig.
D. K. Morris	University College, London	University College, London.
J. Frith ...	Owens College, Manchester	Owens College.
R. Beattie	Durham College of Science	Durham College of Science.
W. B. Burnie	University College, Nottingham	Central Technical College.
J. A. McClelland	Queen's College, Galway	Owens College.
F. B. Kenrick ...	University of Toronto ..	University of Leipzig.
F. J. A. McKittrick	Dalhousie University, Halifax, Nova Scotia...	Cornell University.

Note.—Such of the above Scholars as remained at the nominating Institution for the first year will now proceed to another Institution in England or abroad.

The following scholars, appointed in 1893, have been selected for exceptional renewal for a third year:—

Name of Scholar.	Nominating Institution.	Place of Study.
H. W. Bolam.	University of Edinburgh	University of Leipzig.
J. W. Walker . .	University of St. Andrews	Universities of Leipzig and St. Andrews.
J. E. Myers	Yorkshire College, Leeds	University of Strassburg
E. C. C. Baly ..	University College, London ...	University College, London.

SCIENTIFIC SERIALS.

American Meteorological Journal, July.—The geographical distribution of the maximum and minimum hourly wind velocities . . . for January and July, for the United States, by Dr. F. Waldo. This discussion is based on the Signal Service and Weather Bureau observations, and the subject is treated in various ways, and illustrated by wind charts. We select from these (1) the hour of maximum wind and (2) the maximum hourly wind, in miles per hour. There is no great regularity in the time of occurrence of the strongest wind; in January it occurs on the Atlantic coast from 2h. to 4h. a.m., and on the North Pacific coast it is retarded to 6h. a.m. On the Gulf of Mexico it takes place about noon, while at inland stations it occurs generally about 2h. p.m. In July, on the Atlantic coast, there is a maximum wind about 2h. p.m. in latitude 45°, but with southward progress it is retarded, until in latitude 30° the hour is changed to 6h. p.m. In the southern part of the Pacific coast, the time of maximum is 1h. p.m., which is much earlier than for the adjacent inland or the northern part of the coast. In general, for the inland north-east the hour is 2h. p.m., and there is a retardation with both western and southern progress. In January the maximum hourly wind reaches a velocity of seventeen miles on the northern parts of the Atlantic and Pacific coasts, decreasing with southward progress, while the inland distribution shows a maximum of ten to thirteen miles per hour over the Great Plains. In July, the maximum hourly wind is eleven to thirteen miles on the Atlantic coast, while on the North Pacific coast there is a very small maximum (eight miles), but this is counterbalanced by the very high velocity of eighteen miles per hour on the central Californian coast. A reference to the wind charts shows the prevailing conditions much better than any verbal description can do.

Bulletin of the American Mathematical Society, No. 9. (June 1895, New York).—Mr. J. de Perott gives a very interesting sketch of Euclidian arithmetic in connection with a notice of the late M. Stieltjes' contribution to the *Annales de la Faculté des Sciences de Toulouse*, vol. iv., entitled "Sur la théorie des nombres." M. Stieltjes had it in contemplation to write an extensive treatise on the theory of numbers, but unhappily his weak health and final untimely death prevented his getting beyond the paper noticed by Mr. de Perott. This paper is devoted to a greatly generalised form of Euclid's work. "It does not insist on the definition of number, nor on the laws which are at the base of the operations we perform on numbers, but passes immediately to the exposition of the chief properties of the least common multiple and the greatest common divisor of numbers. . . . Poinsot was the first, I think, to whom it occurred that the course could be reversed." The results are expressed in a very symmetrical form by the author of the note.—Mr. G. L. Brown writes a short note on Hölder's theorem concerning the constancy of factor-groups, and Prof. F. Morley a like note on the theory of three similar figures. The theory has been recently given in the sixth edition of Casey's "Sequel to Euclid," and also in the second edition of his "Conics." Prof. Morley believes that something is to be said in favour of an appropriate analytic handling of the theory, and gives here some preliminary equations in a convenient form.

Bollettino della Società Sismologica Italiana, I., 1895, No. 3.—Microseismograph for continuous registration, by Prof. G. Vicentini (see p. 178.)—New type of seismic photochronograph and its applications, by A. Cancani. A description of an instrument by which the face of a chronometer is photographed at the moment of the shock or of the arrival of long-period pulsations from a distant earthquake.—Review of the principal eruptive phenomena in Sicily and the adjacent islands during the four months January–April, 1895, by S. Archidiacono.—The Viggianello (Basilicata) earthquake of May 28, 1894, by M. Baratta. An account of an interesting tectonic earthquake. The meizoseismal area, which is elliptical and only about 17 km. long, is restricted to the northern slopes of M. Pollino. This group of mountains represents the northern half of a vast ellipsoid of dolomites and limestones, traversed by great fractures, which, if produced, pass through Rotonda and Viggianello, the towns most damaged by the shock. Notices of Italian earthquakes (February–April, 1895).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 22.—M. Marey in the chair.—Researches on the composition of grapes from the principal French vines, by MM. Aimé Girard and L. Lindet.—On the osmotic phenomena produced between ether and methyl alcohol across different diaphragms, by M. F. M. Raoult. It is found that with ether and methyl alcohol on the respective sides of a diaphragm of pig's bladder, the methyl alcohol passes by osmosis to the ether side. The bladder membrane appears to be impermeable to ether: even with mixtures the transference is always of methyl alcohol towards the side where it is of less concentration. Exactly the reverse occurs with a vulcanised caoutchouc membrane, which is impermeable to methyl alcohol, but permeable to ether. The experiments show: (1) that osmosis between two determined liquids may not only vary much in energy, but even change its sense with the nature of the diaphragm; (2) that the osmotic movement of substances

across the diaphragm may be absolutely independent of their molecular weights and of their condition as dissolved substance or solvent.—Action of phenyl isocyanate on some acids and ethereal salts, by M. A. Haller. M. Retzius was elected Correspondant of the Anatomy and Zoology Section, in succession to M. Carl Vogt.—Abnormal refractions at the surface of water, by M. Ch. Dufour. Attention is directed to a source of error, due to irregular refraction caused by differences in temperature between water and air immediately above its surface, which may arise in taking the latitude or determining time at sea.—On static or dynamic explosive potentials, by M. R. Swyngedauw. According to the experiments described, the explosive potential between two poles shielded from ultra-violet radiations is not appreciably diminished by very small and very rapid variations of potential. On a phosphorescence phenomenon obtained in tubes containing rarefied nitrogen after the passage of the electric discharge, by M. Gaston Séguy. In presence of vapours of stannic chloride, the author finds the light emitted from a nitrogen tube to be rose-coloured during the discharge, and milky white for some 10 to 80 seconds after interruption of the current. On the electromotive force of the Latimer Clark, Gouy, and Daniell standards, by M. C. Limb. The values found by the author's method for the elements at 0 C. are: Latimer Clark 1·4535 volts (absolute), Gouy 1·3928 volts (abs.), Daniell (Fleming type) 1·0943 volts (abs.).—On Natterer's tubes, by M. Gouy. On anhydrous crystallised manganese sulphide, by M. A. Mourlot. Crystallised sulphide, identical with *alabandine*, has been obtained by means of the electric furnace. Small cubes or transparent derived octahedra of a greenish shade are obtained. They have the density 3·92 and hardness 3·5 to 4.—On some properties of combinations of ferrous chloride and nitric oxide, by M. V. Thomas. The experiments detailed show that the three compounds obtained by the author in the dry way possess no appreciable tension of dissociation at the ordinary temperature, and hence differ from the compounds obtained in solution by M. Gay.—On some alkaline phosphides, by M. C. Hugot.—Specific heats of superfused formic and acetic acids. Modifications applied to Regnault's thermocalorimeter to enable the determination of the specific heats of a large number of superfused liquids, by MM. Massol and Guillot. The specific heats of formic and acetic acids in the solid state are much greater than their specific heats in the liquid state. The specific heat in the liquid state diminishes with the temperature. When superfused, the specific heat is slightly augmented, but remains of the same order as the specific heat in the liquid state. Synthetic formation of nitro-alcohols, by M. Louis Henry.—Oxidation of inactive campholenic acid, by M. A. Behal.—On the constitution of vegetable albumenoid substances, by M. E. Fleurent. Influence of respiration on the volumetric trace of the limbs, by MM. A. Binet and J. Courtier.—Modifications of the heat radiated produced by faradisation, by M. L. Lecercle. An account of the local rise in temperature [illegible] in animals by electric excitation, and its effect on the general temperature.—Aggravation of the effects of certain [illegible] toxines by their passage through the liver, by MM. J. Teissier and L. Guinard.—A contribution to the histology of unicellular glands, by MM. J. Kunstler and A. Gruvel.—On the [illegible] of the magmas of certain amphibole granites, by M. A. Michel Levy.—On the first alcohol thermometer used in [illegible], by M. l'Abbé Maze.

BERLIN.

Physiological Society, June 7.—Prof. Munk, President, in the chair.—Prof. Baginski reported on experiments made, in [illegible] with Dr. Sommerfeld, on bile from 115 children. [illegible] showed that, in comparison with the bile of adults, it [illegible] more water and mucin and less bile-salts. It contained [illegible] ethereal sulphates, and in the case of children who [illegible] hypothermia it was free from bile-salts. Examination [illegible] children suffering from various forms of nephritis [illegible] an abnormally large amount of xanthin [illegible], which could not be accounted for by any breaking [illegible] or blood corpuscles. Dr. Benda de[illegible] in the mucous membrane of the true [illegible], which cause corresponding furrows in the [illegible] layer. They can be readily brought [illegible] by the removal of the epithelium by macerating in dilute [illegible]. The glands are shorter than the vocal cords, and [illegible] karyokinetic cell-division can often be [illegible] in the [illegible] layer.

June 21.—Prof. du Bois Reymond, President, in the chair.—Dr. Schulz spoke on the anatomy of unstriated muscles in vertebrates. He finds that they consist of elongated cells, pointed at each end, whose length is very variable in different animals. Each cell consists of fibrils imbedded in a highly refractive interfibrillar substance, and of granules and a nucleus in the middle of the cell with two nuclear bodies. Two nuclei in one cell were only seen once among thousands of preparations. The fibrils interlace with each other. The separate cells are not held together by any cement-substance, but by protoplasmic threads and branches. The transverse striation described by many observers appears to be due to a wrinkling of the cell resulting from incomplete extension after having been contracted. Nerve fibres are very plentiful. With methylene-blue, gold chloride, or by Golgi's method numerous ganglion-cells can be brought into view, from which short branches are distributed to the muscle cells. In addition to these numerous nerve-fibrils can be seen ending in minute bulbous swellings which are applied to the muscle. The nerves are sensory as well as motor.—Dr. Cohnstein reported experiments on injecting solutions of sugar into the blood-vessels, in support of his views on the formation of lymph in opposition to Heidenhain. The results were the same as on the injection of salt solutions. The amount of sugar in the blood rose and fell very rapidly, whereas it rose and fell very slowly in the lymph. The maximum of sugar observed in the lymph was equal to the maximum met with at an earlier stage of the experiment in the blood. The solid constituents of the blood became less after the injection, and then increased slowly to the normal; in the lymph, on the other hand, they increased at first and then became less. After the injection of sugar the blood capillaries of a frog's web were considerably dilated and the circulation quickened. Dr. Cohnstein interpreted these results as indicating an initial passage of water from the intercellular spaces into the blood-vessels, followed at a later stage by a return filtration into the lymph. He had also observed a diminution in the secretion of bile after the injection of sugar, and attributed this to compression of the bile capillaries resulting from dilatation of the blood capillaries.

THURSDAY, AUGUST 8, 1895.

THE STUDY OF INSECTS.

A Manual for the Study of Insects. By Prof. John Henry Comstock and Anna Botsford Comstock. Pp. 701. (Ithaca, N.Y.: Comstock, 1895.)

THE present work is very much on the same lines as Dr. Packard's well-known "Guide to the Study of Insects," though somewhat more popular, and dealing still more exclusively with North American entomology, of which, on the whole, it furnishes an admirable compendium. It is got up in a very attractive form, and is crowded with illustrations, the woodcuts being chiefly from engravings from nature by Mrs. Comstock.

The first chapter is devoted to a brief explanation of the principles of zoological classification and nomenclature, in the course of which we meet with a system of trinomial nomenclature for sub-species, or constant varieties, which has not hitherto been much patronised by entomologists. Thus, with reference to a common American swallow-tail, Prof. Comstock writes:

"This name, *Jasoniades glaucus*, is used when reference is made to the species as a whole. But if one wishes to refer to the black form alone, it is distinguished as *Jasoniades glaucus glaucus*; while the yellow form is distinguished as *Jasoniades glaucus turnus*."

Surely this is too complicated and clumsy a system for ordinary use!

The second chapter deals with "Insects and their near relatives," and includes a brief definition of the branch (or, as it is more commonly called in England, sub-kingdom) Arthropoda, and a table of the four classes *Crustacea*, *Arachnida*, *Myriapoda*, and *Hexapoda*, or insects. The *Crustacea* and *Myriapoda* are very briefly noticed, though a few typical forms of each are figured; but the *Arachnida* receive more attention, the orders and principal families, especially of the *Araneida*, being briefly discussed, with notices of their chief peculiarities and habits. As an illustration of the author's style in the more popular parts of his book, as well as embodying a curious phase of cannibalism, we may quote the following passage from p. 24:

"Fig. 23 represents the large egg-sac of one of the cobweavers. This is made in the autumn, and contains at that season a large number of eggs—five hundred or more. These eggs hatch early in the winter; but no spiders emerge from the egg-sac until the following spring. If egg-sacs of this kind be opened at different times during the winter, as was done by Dr. Wilder, the spiders will be found to increase in size, but diminish in number as the season advances. In fact, a strange tragedy goes on within these egg-sacs; the stronger spiders calmly devour their weaker brethren, and in the spring, those which survive emerge sufficiently nourished to fight their battles in the outside world."

The remaining chapters are taken up with a sketch of the seventeen orders of insects admitted by Prof. Comstock, with special, and indeed almost exclusive, reference to the North American species. These chapters differ very much in length and importance, the space allotted to some of the smaller orders being barely a couple of pages, while the chapter on *Lepidoptera* alone occupies nearly a third of the volume.

The interest of the book is much enhanced by the illustrations; and in speaking of the *Membracidæ*, one of the families of *Homoptera*, Dr. Comstock observes: "Nature must have been in a joking mood when tree-hoppers were developed"; and the row of "odd fellows" at the foot of p. 154, where this observation occurs, fully bears out the remark.

But it must not be supposed that this book is too popular to appeal to serious students; far from it. Some of the smaller orders of insects are, indeed, passed over with but slight notice; but in the larger ones, we meet with elaborate descriptions of structure, and dichotomous tables of the principal families, which are afterwards discussed in greater detail, and in most cases one or more of the representative American species are figured, frequently with transformations.

Although, as a rule, America suffers more from insect pests than Europe, yet there seem to be exceptions which we should hardly anticipate. Thus Prof. Comstock informs us (p. 103) that "The earwigs are rare in the North-Eastern United States, but are more often found in the South and on the Pacific coast," and the native American cockroaches also are regarded by him (p. 106) as harmless, the destructive species, as in England, being all imported insects. Among these, he mentions the "Croton Bug," as he calls *Phyllodromia germanica*, as infesting "the vicinity of the pipes of the water-systems of many of our cities." In England, this species is particularly numerous in bakeries.

Under the *Fulgoridæ* (Lantern-flies), Prof. Comstock refers to "the fact that they are phosphorescent," apparently being unaware that the statement is very greatly doubted, though it is perhaps premature to say that it has been actually disproved.

A great many figures of neuration of *Lepidoptera* and other insects are given, all numbered according to a uniform system which Prof. Comstock has adopted from Redtenbacher, with modifications of his own, but which is unfortunately not fully explained in the work before us.

English names are given to most of the insects noticed, some of them being rather grotesque. Thus, at p. 274, we find a figure of "The Firstborn Geometer" (*Brephos infans*), with the explanation on the following page: "As this is probably the most primitive geometer occurring in our fauna, we suggest the popular name Firstborn for it." This is not the first occasion on which we have had occasion to animadvert on the introduction of crude speculations on the course of evolution, as if they were established or probable facts.

It is perhaps worth noticing that Prof. Comstock places the *Lepidoptera* between the *Myrmeleonidæ* and the *Diptera*. He has a peculiar classification of his own, which we have not space to indicate in detail; but he makes the *Hepialidæ* and *Micropterygidæ* a separate sub-order under the name of *Jugatæ*, and after it he places the *Frenatæ*, in which he includes all the remaining families, commencing with the *Megalopygidæ*, *Psychidæ*, *Cossidæ*, &c., and ending with the "super family" *Saturniina*, the "families" *Lacosomidæ* and *Lasiocampidæ* (apparently not referred to any "super-family"), and the butterflies, including the "super-families" *Hesperiina* and *Papilionina*, in a reversed order, terminat-

ing with the Nymphalidæ, sub-family *Satyrinæ*. In the butterflies, Dr. Scudder has been chiefly followed.

The family *Papilionidæ* supplies us with an illustration that the book is only written primarily for American students; for the *Papilioninæ* are distinguished by the black ground-colour, the tail, and the five-branched radius of the fore-wings; and the *Parnassiinæ* by the white tail-less wings and four-branched radius, characters not universally exact, though amply sufficient to distinguish the North American forms.

A curious fact is noticed by Prof. Comstock with reference to the Garden Whites. He tells us that the native American species *Pieris oleracea* and *Pontia protodice* have both become greatly lessened in numbers by the increase of the imported European *Pieris rapæ*.

Another curious fact noticed by Prof. Comstock is that the dog-flea is the common flea of the United States, the true *Pulex irritans* being comparatively rare; while the importance of counter-checks in agricultural entomology is illustrated by the author's remark: "Nothing more wonderful has been accomplished in economic entomology than the subduing in California of the cottony-cushion scale by the introduction from Australia of a lady-bug, *Vedalia*, which feeds upon it."

We cordially commend Prof. Comstock's book to European, and especially to British, entomologists; for, although it is written mainly for American students, it contains much which entomologists of other nations will find both useful and instructive. W. F. K.

AGRICULTURE AND HORTICULTURE.

Agriculture, Practical and Scientific. By James Muir, M.R.A.C. Pp. 350. (London: Macmillan, 1895.)

Agriculture. By R. Hedger Wallace. (London and Edinburgh: W. and R. Chambers, 1895.)

The Horticulturist's Rule-Book. By L. H. Bailey. Third edition. (London and New York: Macmillan and Co., 1895.)

PROF. MUIR'S neat and presentable volume is the latest claimant upon the indulgence of the agricultural public, the number of readers—and what is more to the point, the number of students—amongst whom is undoubtedly steadily increasing. Commencing with a discussion of the plant, the author speedily falls back upon the soil as the staple of his discourse, though parenthetically he introduces a chapter on plant food in the soil. Then we get the inevitable section on the British geological formations, which has about as much relation to the living art of agriculture as a list of our kings and queens has to a true understanding of English history. Drainage, irrigation, and other processes for ameliorating the soil are next discussed, and then half a dozen chapters are devoted to the important subject of manures. Implements and machines are next briefly glanced at, and the remainder of the book is occupied by chapters on the chief crops of British agriculture. We believe that, well-worn as the theme is, there is still room for novelty in the treatment of agriculture as a book subject, but Prof. Muir does not appear to have hit upon it.

Live stock constitute the backbone—the sheet-anchor of British agriculture, and to omit all reference to this indispensable section of our greatest national industry in a book bearing the comprehensive title of the volume under notice, is a blemish upon the work. No one would ever infer from its name that the volume is silent upon the great subject of sheep husbandry, which has become so inextricably—and we may add so advantageously—interwoven with the arable farming of this country. Nor would any one expect, in a book on "Agriculture, Practical and Scientific," to find no allusion to the milk-pail and the cows that fill it, and no mention of the butter and cheese industries. The author recognises that agriculture embraces "the breeding, feeding, and management of all kinds of farm live-stock," but it is not till the reader begins perusing its pages, that he learns that the work "will not attempt to deal with" this part of the subject. In this matter, the author had nobody but himself to please, and all we venture to say is that the title of the volume should have fitted its contents. A work on "agriculture" that ignores live-stock might fairly be compared to a treatise on chemistry that made no mention of carbon.

The part of the work that is best done is that relating to crops, and had Prof. Muir chosen to confine himself to this branch of farming, he would not have acted unwisely. His skilful treatment of this section of the subject serves to revive the recollection of John Wilson's admirable work in the middle of the century. But the most important cropping of all—that of grass land—is inadequately treated, though it is abundantly evident, from the few pages allotted to this subject, that the author might usefully have given more space to it at the expense of one or two perfunctory chapters which would not have been missed. The processes of hay-making and ensilage are well described, yet here again the idea arises that the author felt he was approaching his limits, and the result is that he appears to exercise a restraint which we feel sure has operated to the disadvantage of the reader. A feature of the work that will be much appreciated is that it reproduces in a handy form many of the tabular statements that have from time to time been published in the *Journal* of the Royal Agricultural Society of England. Three dozen illustrations accompany the text, and those of seeds are particularly noteworthy for their fidelity.

Commending the book, then, for its trustworthy treatment of farm crops, we may notice one or two features that seem to call for criticism. The index is sometimes relied upon for the introduction of terms not given in the text. Thus, "nitrification" is indexed as dealt with at page 25, turning to which the reader finds the process described, but no name given to it, unless perchance the term "oxidation" is inadvertently used instead. Other similar cases occur. A highly important subject to farmers, the temperature of germination, is surely awarded scant treatment when it is dismissed in the brief paragraph: "The temperature most favourable to germination varies in the seeds of different plants." Such frequent recourse is made by the author to the work of Lawes and Gilbert, that it is regrettable he did not imitate the consistency with which they employ the term "nodules" to denote the outgrowths on the roots of papilionaceous plants. The repeated use of the word

"tubercle" can only lead to confusion, especially now that, in connection with bovine and other tuberculosis, it is so frequently heard at agricultural gatherings. Several peculiarities in spelling, adhered to throughout the work, might in a new edition be brought into conformity with general usage: examples are afforded in *Telletia*, *Cecydomyia*, *Centorhynchus*, *Siton i*, *Chonopodium*, *Claviceps purpura*.

It is difficult to understand why the second of the volumes of which the titles head this notice has been prepared, unless it be to find favour with candidates in a certain specified examination, the syllabus of which, however, the author tells us, "has not been slavishly followed." The really valuable parts of the book have apparently been culled from the writings of five living agricultural authors whose names are mentioned in the preface, and who, if they turn over the pages of this compilation, can hardly fail to alight upon much that they have seen before. It is regrettable that the author did not cling to his guides throughout. He would not in that case have said of sainfoin: "In appearance the leaves resemble those of vetches, but the blossom is more like that of red clover." Apart from the worthlessness of such a statement as this, it cannot fail to raise a doubt as to whether the author has ever seen a field of sainfoin. Again, with reference to lucerne, we read: "Like sainfoin, it produces good crops for about ten years." Where, we would ask, is the district in which sainfoin stands for anything like this period? What is meant by the statement that "sainfoin is much harder than lucerne"? The germination of a seed is described as "the period parallel to the sucking of a young mammal"; and elsewhere we read, "nitrification goes on or acts more quickly under circumstances favourable for rapid growth, and in this respect is parallel to germination." Nothing, perhaps, indicates the character of the book more thoroughly than the page of illustrations entitled "Various Specimens of ——s Grass Seeds." We omit the name of the seedsman, who probably would be sorry to claim that a seed of rye-grass, for example, sold by him is different from all other rye-grass seed.

The 350 pages of the book are divided into no fewer than 70 chapters. *Inter alia* a treatise on chemistry is introduced, with figures of a spirit-lamp and test-tube. From a chapter on "Blossoms and their functions," we cull the following specimen of literary grace: "We are apt to look upon them merely as objects created to feast man's eye with their beauty, or his nose with their sweet scent." The language of the book is of an irritating style, which is constantly in evidence from the grammatical blunder at the close of the preface down to the final chapter, in which reference is made to what "the plant needs to live healthy." It is, however, only fair to add that, at the outset, the author writes: "It has been my endeavour to avoid errors."

The sub-title of Mr. L. H. Bailey's book "A compendium of useful information for fruit-growers, truck-gardeners, florists, and others" indicates its scope. In a score of chapters such subjects are dealt with as injurious insects, insecticides, plant diseases, fungicides, lawns, grafting, seeding, storing of fruits and vegetables, the weather, and many other matters of practical interest. It is stated in the preface: "The contents of the volume have been gleaned from many sources; and, whilst the compiler cannot assume the responsibility of the value of the many recipes and recommendations, he has exercised every care to select only those which he considers to be reliable." The result is a most valuable book, and though intended primarily for American readers, it will none the less constitute a useful reference manual for horticulturists in this country. We notice, with regard to potato disease, that it is recommended to spray the plants with Bordeaux mixture "upon the first indication of the blight." It would probably be better to follow the advice, recently published by the Irish Land Commission, to spray before the appearance of disease, and thus employ the application as a preventive rather than a remedial measure. It is when the reader meets with such a remark as the "marsh-marigold or so-called cowslip," that he must bear in mind the American origin of the book. There is probably no better work of its kind.

OUR BOOK SHELF.

Electrical Laboratory Notes and Forms. Arranged and prepared by Dr. J. A. Fleming, F.R.S. (London: The *Electrician* Printing and Publishing Co.)

It is now generally recognised that the best way to teach the rudiments of science is by the natural or kindergarten method, which aims at leading the young student to observe facts and phenomena for himself, and come to conclusions concerning them. The method is applied easily enough to very elementary practical work, and with the best results. In the case of elementary work in physics, all the student requires to be told is what to do, and he may be left to find the teaching of his results. For instance, it is only necessary to instruct him to find the weights of equal bulks of different liquids and solids, and the results of his experiments show him at once what relative density means. This principle of letting the results of experiments suggest conclusions is undoubtedly the right one for introductory courses of practical physics and chemistry; indeed, almost the only information that need be given to the students in the laboratory is how to set up their simple apparatus and what to do with it; nothing ought to be said about what they are going to prove, or the experiments lose their value of developing the faculties of acute observation and intelligent induction from the observed facts.

Advanced work in physics and chemistry offers difficulties to the extension of the scientific method of observation and induction. The time spent in the laboratories is far too short to enable students to rediscover the more intricate laws and relationships for themselves, however admirable the mental training of such researches may be; and if the instruments are all arranged so that it is only necessary to press a knob to make them act, and obtain a result, the value of the mechanical observations then made cannot be very great. The difficulty of applying the scientific method to physical laboratory work is brought out by the volume before us. The volume contains twenty elementary and twenty advanced exercises in electrical measurement. Each exercise consists of a six-page sheet, two pages of which are occupied with a condensed account of the theoretical and practical instructions for performing the particular experiment, while the remaining pages are ruled up in lettered columns, to be filled in by the student with the results of his observations. What the student does

is really to test the accuracy of formulæ, mostly arrived at by theoretical considerations; the work is therefore purely deductive, and not inductive. Yet it is difficult to see how to make the work covered by these notes anything but deductive; certainly no better system of teaching practically the elements of electrical engineering has so far been developed.

By means of Dr. Fleming's notes and a little oral assistance now and then, the student will be able to perform instructive experiments, and will be taught to observe closely, and to record his results neatly. The method followed facilitates the work of the demonstrator and the student, and enables a large amount of practical work to be carried out in a comparatively short time.

Microbes and Disease Demons. By Dr. Berdoe. Pp. 93. (Swan Sonnenschein and Co., 1895.)

Under the above sensational title the writer discusses, or rather attacks, the anti-toxin treatment of diphtheria. It is difficult to understand what has prompted the production of so prejudiced and, we regret to say, unscientific comment upon this subject. We most emphatically take exception to such expressions as "scientific quackery," and others of a similar character, being applied to investigations of which, although the therapeutic value may be as yet a question of opinion, undoubtedly mark a new step forward in our endeavour to unravel the problems surrounding disease.

We have no intention of discussing Dr. Berdoe's views in detail, but we feel ourselves called upon to refer to one statement, because the writer has used it as a vantage ground for his most savage attack upon this method of treating diphtheria. We refer to the death in Brooklyn alleged to have resulted from the injection of some of the anti-toxin. Several pages are devoted to a detailed account of the incidents of the case, and Dr. Berdoe does not hesitate to designate it as "sudden death from anti-toxin." This, however, is not the view of the Brooklyn Health Department, or of authorities in the Bacteriological Laboratory of the New York City Board of Health, in both of which institutions the anti-toxin used was submitted to a very careful and exhaustive examination, and the official opinion given that it was not responsible for the death of the patient.

The case for or against the anti-toxin treatment of diphtheria is not one which should be approached from a party point of view, and such prejudiced, vaporous effusions as Dr. Berdoe has permitted himself to indulge in, will never take any part in deciding the question of its efficiency. To arrive at any such positive conclusion is of necessity a matter upon which time and experience can alone give the final verdict, and its discussion should only be entrusted to those who are capable of approaching the subject in a scientific and judicial spirit.

Men gu-yu-mu-tsi: or, Memoirs of the Mongol Encampments. Translated from the Chinese by P. S. Popov, Russian General Consul at Peking. 580 pp. *Memoirs of the Russian Geographical Society*, vol. xxiv.: (Russian.) (St. Petersburg, 1895.)

This is the work of two Chinese men of science, Chjan-mu, or Shi-chjou, author of a history of Jinghiz khan's conquests, and Khe-tsyu tao, author of several geographical works, of which the description of the northern borderland is best known. It was published in China in 1867, and consists of two parts: a description of the different tribes and confederations into which the Mongols are divided, with short notes on the extent of the territories they occupy, and short historical notices—the whole covering only about 160 pages of the Russian edition—and a great number of most interesting footnotes, which cover more than two thirds of the volume, and contain a great variety of miscellaneous geographical and historical information.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

University of London Election.

I have read the letters which Mr. Bennett, Mr. Thiselton-Dyer, and Prof. Ray Lankester have addressed you on the subject of the University of London, and much regret that my friends, whose opinion I value so much, take exception to one paragraph in my letter to Prof. Foster. I do not wish to seem to treat their views with any want of respect, and perhaps, therefore, you will allow me to send a few lines in reply.

They all criticise the sentence in which I state that I should endeavour to maintain the right of Convocation given in the Charter, which expressly provides that no alteration should be made in the constitution of the University without the assent of Convocation.

Prof. Ray Lankester says that "Sir John Lubbock has adopted and made himself the leader of this extraordinary and fantastic policy." Whether it is extraordinary and fantastic or not, is of course a matter of opinion, but, at any rate, it is the law at present.

I am satisfied that my constituents highly value this right, and I fail to understand how Mr. Thiselton-Dyer has been able to persuade himself that in endeavouring to maintain it I am taking a line "not courteous to Convocation," or have given "Convocation the severest slap in the face it has ever received."

Prof. Ray Lankester also says that I "have shown an unfavourable estimate of the intelligence" of my constituents. This is such an extraordinary version (not to say perversion) of what I said, that I trust you will allow me to quote my own words. What I said was—

"Feeling that Convocation ought to be consulted on a matter so vitally affecting the University, I should strongly urge, and would do my best to secure, that the scheme when arranged should be submitted to Convocation for their approval, to be signified as at a senatorial election, and would oppose the Bill unless this were conceded."

Why should this proposal appear to my friends as being, in Mr. Bennett's words, fatal to "all hopes of bringing our University into line with the requirements of the age"? The Commissioners will either propound a wise scheme or an unwise one. My critics believe that it will be wise. Why, then, should they assume that Convocation will reject it? At any rate it is an extraordinary reason for attacking me as a Member of Parliament, that I have faith in the good sense and sound judgment of my constituents.

John Lubbock.

High Elms, July 30.

Metrical Relations of Plane Spaces of n Manifoldness.

Plane spaces of n manifoldness are assumed to have the following properties:

(1) Given a S_{n-1} (a plane space of $n-1$ manifoldness) and a point P outside the same, then a certain S_n will exist which contains both the S_{n-1} and P.

It follows therefore that a S_n is determined by $n+1$ of its points, unless these points have that special situation to each other by virtue of which they are contained in a plane space of minor manifoldness.

(2) If a plane space S_m contains $n+1$ points, which have not the special situation to each other above mentioned, then it will contain the plane space S_n, determined by these points.

It therefore appears that $n+1$ points determine a S_n uniquely.

Given a straight line L and any point P upon the same: through L any number of planes can be constructed, each of which contains a certain line L′ through P perpendicular to L. The aggregate of such lines L′, in a space S_n form a S_{n-1}, which has that special position towards L by virtue of which it is called perpendicular to L in P.

To prove this theorem, which certainly holds if $n=2$ or 3, let us assume that it is true when $n=k$; then it will also be true when $n=k+1$. Through P, in a space S_k which contains L and is contained by S_n, construct the S_{k-1} perpendicular to L. Any point not contained in the S_{k-1} and L determines a plane,

which contains the perpendicular PQ to L. PQ and the S_{k-1} determine a space S_k, and the proposition is that any line through P in this S_k is perpendicular to L. Through PQ construct a plane space Σ_{k-1} in S_k perpendicular to L. It must exist, according to hypothesis. S_{k-1} cuts the S_k into two parts, because every straight line in S_k (as easily follows from the assumptions) has one point in common with the S_{k-1}, we therefore have no means of passing from one point of such straight line to its other points without passing the S_{k-1}. S_{k-1} and Σ_{k-1} cut the S_k therefore into four different parts, which have the cut of Σ_{k-1} and S_{k-1}, that is a certain S_{k-2}, in common. Let the four departments, into which the S_k is cut, be called A, B, C, D. A straight line through P, not contained by the S_{k-2}, will be situated (as it passes P, that is a point of the S_{k-2}) in two different departments; and if we change the situation of this line continuously, without passing either the S_{k-1} or the Σ_{k-1}, it will remain in the same two departments. The departments are therefore arranged by two. If a straight line through P, belonging to A, also belongs to B, then A and B shall be called opposite to each other. Let A, B and C, D be opposite to each other. We have no means whatever of distinguishing two opposite departments, unless we assume at the very least another arbitrary point, because every plane configuration through the S_{k-2}, extending into one department, equally extends into the opposite one. Whatever is true for the one department must therefore be true also for the opposite one.

Now construct any line L′ through P in the S_k. Let L′ belong to A and B. If L and L′ are not perpendicular, then the angle LL′ contained in A must be larger or smaller than the corresponding angle LL′ contained in B. Let L′ change its position continuously; if the angle LL′ contained in A would be always larger than the corresponding angle in B, this would amount to a permanent property of A distinguishing it from B, which it cannot possess. Therefore, whichever evolution L′ may perform from the S_{k-1} to the Σ_{k-1} in A (and B), it must have at least one intermediate situation in which L and L′ are perpendicular. The aggregate of such situations form a surface in A and B. Let L', . . . L'_{k-1} be $k-1$ lines contained in that surface; then the plane space of $k-1$ manifoldness containing these $k-1$ lines, must, according to the hypothesis, be perpendicular to L. The surface must therefore contain this plane space. If now we replace one of the two S_{k-1} or Σ_{k-1} by this space, the argument will still hold. However, near the two borderings plane spaces will finally approach, there will always be at least one intermediate plane perpendicular space, all of which are contained in the S_k. It is therefore nothing left but to concede that the S_k in question has the property established in the proposition.

Through any point P only one line L will pass, which is perpendicular to a space S. Assume indeed two such lines, which may have with S respectively Q and R in common. Then PQR would form a triangle, of which ∠ PQR as well as ∠ PRQ, according to the foregoing, will be = a right angle. This, however, is impossible, unless Q and R coincide.

A point and a plane space therefore determine a certain line, the perpendicular to that space through the point, a certain point—the one in which the line above mentioned cuts the space—and a magnitude, the distance of the two points above mentioned. This is always true, unless the point belongs to the space. Let the point approach the space. If the two points in question coincide, then the point will belong to the space. The conditions, therefore, that a point and a space are united, is (distance of point and space) = o.

Let P move continuously so that its distance from a plane space S remains unaltered; P and S may determine a space Σ; then the aggregate of such points in Σ is another plane space. Let P and Q be two situations of P. Then all points of the line PQ have the same distance from S, as is easily seen to rest on Euclid's parallel axiom by means of parallelograms. The general proposition can, from this, be established by considerations analogous to the proof of our first theorem, independent of any new assumption. Two such spaces Σ and S are called parallel, and determine a certain magnitude, whose disappearance is the condition of coincidence of Σ and S.

Let Σ and S be parallel. Through any point A outside the same draw two lines, which cut both Σ and S, in B, C and B′, C′ respectively, then the lines ABB′ and ACC′ have a point in common, they are therefore in the same plane, BC and B′C′ must therefore either have a point in common, or be parallel. A point in common they have not, as they are contained in Σ and S, and these two have no point in common. It follows that

$$AB : AB' = AC : AC'.$$

We now add to our assumptions another one. $n+1$ points determine, as already stated, a plane space S_n, and besides a certain pyramid of n dimensions; of which we assume that it shall possess magnitude. Let the $n+1$ points be A_1 . . . A_{n+1}. A_2 . . . A_{n+1} determine a certain space S_{n-1}. Draw any line through A_1. It cuts S_{n-1} in a point B. Choose A'_1 on this line so that $A_1B = BA'_1$. Then the two points A_1, A'_1 have an exactly symmetrical position to S_{n-1}. No property can be valid for the one which is not valid for the other (as long as no elements are introduced to disturb the symmetry). We cannot therefore assume that one of the two pyramids, determined respectively by A_1 and the A_2 . . . A_{n+1} or A'_1 and A_2 . . . A_{n+1}, should be larger than the other. Now the *locus* of points A'_1 is, according to the foregoing, a parallel Σ_{n-1} to S_{n-1}. It follows: The magnitude of the pyramid is dependent (1) on n of its points (2) and the distance of the $n+1^{st}$ from the plane space determined by these n points.

What we have in mind, when we speak of the magnitude of a pyramid, will come out clearer when we give a theorem of addition. Let X be any point collinear with and intermediate between A_2 and A_3. Then we say:

The pyramid determined by A_2X and any other points + the pyramid determined by XA_3 and those other points = to the pyramid formed by A_2A_3 and the rest of the points.

This explanation, combined with the above, shows that the magnitude of a pyramid is equal to some constant multiple (say $\frac{1}{n}$) of the product of the magnitude of the pyramid A_2 . . . A_{n+1}, and the distance of A_1 from the space fixed by the other points. We shall write this number $(A_1A_2 \ldots A_{n+1})$. (A_1A_2) is simply the distance of the two points, and according to a convention necessitated by considerations of continuity, we assume

$$(A_1A_2) + (A_2A_1) = o.$$

Generally, if we transpose any two letters, the magnitude designated changes sign.

If A, B, C are three collinear points, and if we designate by the single letters A, B, C the distances from these points of any fixed point O on that line, then we have identically

$$(AB)C + (BC)A + (CA)B = o.$$

This is an algebraical identity easily established. The same holds also when the single letters A, B, C are made to denote the distance of these points from any space Σ, which either is parallel to line ABC, or has with it a point in common, as is easily established by proportions.

If between three points of a line such an equation exists, this must be true also for $n+2$ points in a S_n. The proof of this by induction is perfectly easy Let for instance A, B, C, D, be four points in a plane, and let Σ be any space, that has with it a line in common. Join CD; it may meet AB in E. Then we have some linear identity

$$aA + bB + cE = o$$

where a, b, c denote constants independent from Σ, and also

$$dC + eD + fE = o.$$

Eliminating E, we obtain some linear identity between

A, B, C, D.

In order to determine the constants, let us assume the space Σ (which is permitted) to be parallel to the plane ABCD; then we have if

$$aA + bB + cC + dD = o$$
$$a + b + c + d = o.$$

If we place Σ so that it cuts ABCD in CD, and if then we make $a =$ (BCD), c follows = (CDA). We therefore obtain

$$(BCD)A + (CDA)B + (DAB)C + (ABC)D = o$$

and just so in the general case

$$(BCD \ldots L)A + (CD \ldots LA)B + (D \ldots LAB)C + \ldots = o.$$

The use of the distances of points from variable plane spaces enables us to do away with fixed coordinate systems. The proof of projective theorems becomes perfectly lucid, while at each stage of the proceedings we are always able to give the geometrical significance of the constants employed. To give a

few instances: Let $A_1 \dots A_{n+1}$ be $n+1$ points in a plane space S_n. Let P be any other point. We then have one linear relation

$$a_1A_1 + a_2A_2 + \dots + a_{n+1}A_{n+1} + pP = 0.$$

Assume outside the space any point Q. Construct the plane spaces $QA_1 \dots A_n, QA_2 \dots A_{n+1}, \dots$ $n+1$ in all, and cut them by some line joining the residual point $A_{n+1}, A_1 \dots$ respectively with a point R on the line QP. We thus obtain $n+1$ new points $A'_{n+1}, A'_1, \dots$, which joined give a plane space Σ_n, that cuts S_n always in one and the same plane cut S_{n-1}, however we may choose Q and R, which is related to P and the configuration of the A in a peculiar manner.

To follow the different steps indicated, let us assume

$$pP = qQ + rR$$

(the three points are collinear); therefore

$$a_1A_1 + a_2A_2 + \dots + qQ + rR = 0.$$

Joining R with A_1, we obtain a line that contains the point $\frac{a_1A_1 + rR}{a_1 + r}$, which as

$$a_1 + a_2 + \dots + q + r = 0$$

is also $= -\frac{a_2A_2 + \dots + qQ}{a_2 + \dots + q}$, that is contained in the plane space $A_2A_3 \dots Q$.

$$A'_1 \text{ is therefore } = \frac{a_1A_1 + rR}{a_1 + r}.$$

Just so

$$A'_2 = \frac{a_2A_2 + rR}{a_2 + R}.$$

The line $A'_1A'_2$ contains the point

$$\frac{(a_1 + r)A'_1 - (a_2 + r)A'_2}{a_1 - a_2};$$

that is

$$\frac{a_1A_1 - a_2A_2}{a_1 - a_2},$$

which is collinear with A_1, A_2. The plane space S_{n-1} contains therefore all the $\frac{n \cdot n+1}{1 \cdot 2}$ points thus formed, and the proposition follows at once.

In a similar way it may be proved that, if two $(n+1)$ pyramids in a S_n are in perspective, the intersection of corresponding sides, $\frac{n+1 \cdot n}{1 \cdot 2}$ in all, are all contained in a S_{n-1}. We prove this simply for $n = 2$, which is sufficient to exhibit the general way of proceeding. Let ABC, A'B'C' be two triangles in perspective; let AA', BB', CC' have point P in common. Then we must have

$$\begin{aligned} P &= aA + a'A' \\ &= bB + b'B' \\ &= cC + c'C'. \end{aligned}$$

Join AB, A'B'. Their intersection, from

$$aA + a'A' = bB + b'B'$$

follows

$$\frac{aA - bB}{a - b} = \frac{a'A' - b'B'}{a' - b'}.$$

Now $\frac{aA - bB}{a - b}, \frac{bB - cC}{b - c}, \frac{cC - aA}{c - a}$, are obviously collinear.

Two plane spaces in general do not determine one magnitude only. Take, for instance, two lines in space. They have a distance, and form an angle. If their distance or the sine of their angle is = 0, they will be coplanar. If both are = 0, they will coincide. We have two magnitudes, because the system of two lines in space has two degrees of degeneration (coplanarity and coincidence). This is also generally the case, because geometrical magnitudes are nothing but the most suitable invariants, whose evanescence is the necessary and sufficient condition for the degeneration of the system to which they belong.

If two plane spaces A, B determine only *one* magnitude, we designate the same by (AB). Let A be a straight line, for instance, and B a plane space which has one point in common with A. From any point of A, say P, draw the perpendicular to B. Join B with point Q, common to B and A. Then the sine of (∠Q) is the magnitude denoted by (AB). Let A be a plane, having in common with B a line. From any point P of the plane draw the perpendicular on B, say PB, and from this point B the perpendicular on the common line BQ. Then again sin (∠Q) = (AB), and thus generally. We determine the sign of the magnitude according to the rule

$$(AB) + (BA) = 0.$$

Let us now add another plane space C to the system A, B, such that both CA and CB determine only one magnitude. Then the whole system may determine an additional one, whose evanescence would signify that C belongs to the plane space fixed by A and B in conjunction, and is united with the space that A, B have in common. It is in fact the product of (AB) and the magnitude formed by C and the space AB, and will be written

$$(ABC)$$

In this way we proceed, obtaining the definition of a magnitude, which has the property that its evanescence is the necessary and sufficient condition for the degeneration of the system to which it belongs.

The magnitude in question may be formed in various ways, but the system being such that it can possess only one such magnitude, the different formations must always lead to one and the same result, with the exception of a constant factor. This factor must either be + 1, or else − 1, on account of the symmetrical way in which the magnitude is formed. If the system is one of straight lines through a point P, the magnitude in question has a special significance. Two triangles which have an angle in common, are in proportion as the product of the sides including this angle. Three lines in space which have a point in common and are not coplanar, form a corner. Cut a corner by two different planes. The two different pyramids are in proportion as the product of the three sides forming the corner. And so in general, as can be easily proved by induction. Therefore, if we have such a corner of n lines in a space S_n, and cut it by a space S_{n-1} the pyramid formed is = the product of the n sides extending from the vertex of the corner multiplied with a factor which is specific for the corner; and this latter factor is exactly the magnitude formed according to the rule given.

(It may happen that the formation of the magnitude, as given, leads to zero without giving a significant result. This is an indication that somewhere during the process one of the conditions of degeneration is fulfilled—for instance, when C belongs to the space AB. Then the process is the reciprocal one. We determine the magnitude formed by C and the space common to A and B. If that also is zero, then A, B, C belong to what is called a pencil. The simplest case of this kind is the system of three lines in a plane.)

Let A B C be three plane spaces belonging to a pencil: that is, let (ABC) = 0. Let D be any other plane space, which has an element with the pencil in common. Then we have again

$$(AB)C + (BC)A + (CA)B = 0,$$

where the single letters A, B, C in this identity denote the magnitude formed between each of these three spaces and the auxiliary one.

It will suffice to prove this for the case of three lines through a point P. Let Σ cut the pencil in a line S. Let A, B, C form with S the angles α, β, γ respectively, then the proposition amounts to

$$\sin(\alpha - \beta)\sin\gamma + \sin(\beta - \gamma)\sin\alpha + \sin(\gamma - \alpha)\sin\beta = 0,$$

which is nothing but the Ptolemaus theorem about four points in a circle.

Now again we may proceed to show, that between $n+2$ elements A_i, for which, to be short $(A_1A_2 \dots A_{n+2}) = 0$, a linear relation must exist $\Sigma a_i A_i = 0$, where the a_i are certain constants. Of course, if not also some of the minors are zero, such as $(A_1A_2 \dots A_{n+1})$, this will be the *only* relation that can thus exist. We can therefore determine the a_i, by giving Σ exceptional positions. The result is again

$$(A_1A_2 \dots A_{n+1})A_{n+2} + (A_2A_3 \dots A_{n+1}A_{n+2})A_1 + (A_3 \dots A_{n+2}A_1)A_2 + \dots = 0.$$

Let $A_3 \dots A_{n+2}$ form the space S, and the magnitude (S) then, making Σ identical with S, we obtain

$$(A_2S) \cdot (S)A_1 + (SA_1) \cdot (S)A_2 = 0.$$

But $(A_2S) = -A_2$ for this special position of Σ, and $(SA_1) = A_1$, therefore the test applies, and the theorem must be correct.

For such systems A_r as we have considered, all projective properties will be corresponding to each other, and all metrical properties at least as far as they are dependent upon the interpretation of the constants employed. EMANUEL LASKER.

Ilkley, July 9.

P.S.—The same holds true, with slight modifications, for the only curved space that contains no exceptional elements, that is the surface of a globe of n manifoldness.—E. L.

The Feigning of Death.

THE discussion, a few months since, of the feigning of death in reptiles (vols. li. pp. 107, 128, 223, and lii. p. 148), induced me to experiment on the Currant Moth, whose powers of "shamming" are so familiar. The moth was first seized by one wing, and it at once feigned death; thereupon I cut off its head with a pair of scissors, and the *animal continued to feign death*. I use the expression advisedly, for absolute immobility was maintained for some seconds, and then violent fluttering ensued, causing the animal to rush wildly about the table, but failing to lift it into the air. In this condition any impulse, such as touching or pinching, induced a repetition of "shamming." After a strong stimulus the shamming was prolonged, and indeed a direct connection was obvious between the strength of stimulus and the length of period of quiescence. This power of response to stimulus was maintained for two days, and then weak fluttering set in for some hours, followed by death. Our entire ignorance of the physiology of the nervous system of insects renders it difficult to draw complete conclusions from these phenomena; nevertheless, it is difficult to conceive that volition can persist for forty-eight hours in a decapitated animal. We are forced then to conclude that here, at any rate, death-feigning is a purely reflex phenomenon, and that the sensory stimulus received by the surface of the body causes inhibitory impulses to arise reflexly from the ganglia of the central nerve chain, and prevent all movement of the locomotor muscles. In confirmation of this, it may be mentioned that denuding the wing of its scales over any area caused a marked diminution of sensitiveness over the area so treated. Since all stages between sensory hairs and ordinary scales occur in Lepidoptera, it is not unreasonable to assume that the scales still function as tactile end-organs, in spite of their modification subserving decorative purposes. OSWALD H. LATTER.

Charterhouse, Godalming, July 31.

Halley's Chart of Magnetic Declinations.

IN NATURE for May 23 and 30, 1895, are interesting communications from Dr. Bauer and Mr. Ward in reference to Halley's old chart of magnetic declinations.

I have a copy of this chart not referred to by either of these gentlemen.

It is bound in vol. i. of "Miscellanea Curiosa." This work was edited by Halley; it consists of three volumes, containing, in the main, reprints of papers read before the Royal Society. Vol. i. was published in 1705, and was printed by J. B., for Jeffery Wale and John Senex.

The chart is $7\frac{1}{2}$ inches high and 13 inches long, and embraces just the circumference of the earth.

The title in the upper left-hand corner reads: "A new and correct Sea Chart of the Whole World, showing the Variations of ye compass as they were found Año 1700 with a view of the General and Coasting Trade Winds and Monsoons or shifting Trade Winds by the Direction of Capt. Edm. Halley."

In the lower left-hand corner is the note: "Capt. Halley's map of the World in two large sheets is sold by R. Mount and T. Page on Great Tower Hill, London."

The name "I. Harris, delin. & scu." is in the lower right-hand corner of the chart. CHARLES L. CLARKE.

New York, July 27.

THE ERUPTION OF VESUVIUS, JULY 3, 1895.

THIS recent disturbance at Vesuvius is interesting in several ways, and at one time had all the appearance of developing into as grand a display as that of 1872.

The last eruptive cycle of Vesuvius commenced on June 7, 1891, when I had the good fortune to be but a few hundred yards distant at the time the main bursting of the rift took place. The details of that eruption, with illustrations, can be referred to in my articles and reports.[1] We may briefly state that cycle as follows: the splitting of the whole of the great cone of Vesuvius by a radial rift which extended beyond the base for some distance across the Atrio del Cavallo. At the first moment a little lava issued from the upper part of the rift, but after a few hours all came from its lowest extremity in the Atrio, and continued to flow with practically no interruption for a period of nearly three years, or, more correctly, from June 7, 1891, to February 7, 1894. During that period no great quantity was given forth at any one time, so that no stream could attain much length before cooling. Though the amount emitted during that period is enormous, and if vesicularised into pumice and scoria would, I think, quite equal Monte Nuovo in volume. The consequence of this is, that a great and pure lava cone was built up in the Atrio, of low inclination (14°), and adding much to obliterate that interesting and characteristic feature of the volcano. Coincident with the formation of the rift, the central cone rapidly crumbled in, until a deep crater was formed which eventually attained over 150 m.

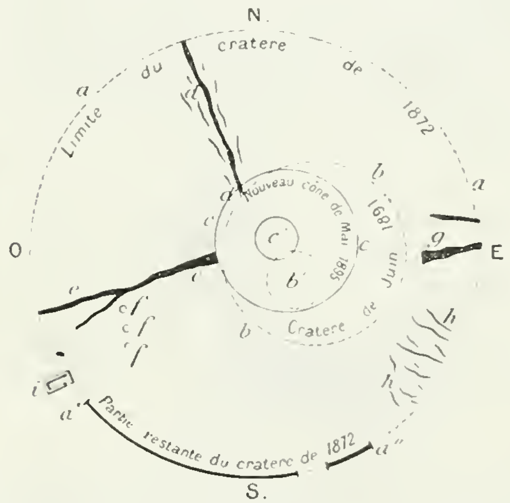

FIG. 1.—Diagram showing the actual state of Vesuvius, from a drawing by M. A. Bourdariat, after an earlier plan of mine (*La Nature*, June 8, 1895). (*a*) Limit of the crater edge of 1872; the part represented by a dotted line is that covered by more recent lavas of different dates. The parts *a*′ and *a*″ are still uncovered. (*b*) Crater of June 1891. (*b*′) Active vent of the 1891 crater. (*c*) New cone in process of formation (May 1895). (*c*′) Active vent of the cone on May 12, 1895. (*d*) Rift and vapour mouth of June 7, 1891. (*e*) Fissure emitting acid vapours on crater plain formed in the 1872 crater. (*f*) Very old hot-air passages and fumaroles. (*g*) Fissure of May, 1889. (*h*) Numerous fissures on the south-east edge of the crater plain. (*i*) Guides' shelter.

in depth and diameter. It was at its greatest dimensions in February 1894, when the lava stopped issuing by the lateral outlet, and therefore commenced to rise in the chimney. The immediate result of that stoppage was that the formation of a cone was soon commenced at the bottom of the crater by the ejection of lava cakes. The growth of this new cone of eruption was so rapid that, when I visited and photographed the interior of the 1891 crater in November last, this was not above 60 or 70 m. deep, and the cone of eruption was rapidly increasing in height within it.

My friend M. Alex. Bourdariat has carefully observed the

phenomena of the volcano during the early months of the present year, and has recorded the changes in *La Nature*, June 8 (Fig. 1). It appears from his interesting description that in January of this year the apex of the cone of eruption overtopped the edge of the 1891 crater. Lava even flowed out in the crescentic depression between eruptive cone and crater ring. This was followed by a little repose of some days, to be succeeded by powerful ejections of lava cakes to a considerable height (80 to 100 m.), which rapidly added to the growth of the eruptive cone. In May, this new cone was from 15 to 20 m. above the 1891 crater, and at the commencement of July was considerably more, as is shown by Fig. 2, taken from San Giorgio a Cremano, as the others (and also notes) by Mrs. T. R. Guppy.[1] This sketch shows that on the day preceding the eruption, central activity with cone-forming stage was very active, attaining the fifth degree on my scale.

M. Bourdariat's plan of the summit of the great cone, constructed on one of mine of earlier date, shows the axis of the new eruptive cone is not concentric, but to the north-west of the 1891 crater. This he attributed to the wind, no doubt one of the causes at work, but I had seen such displacement to be the case in November last, when from the depth of the cone top within the enclosing crater walls these sheltered the falling cakes from the wind. There was evidently even then the radial fissure directed to the north-west in process of formation, which has now been the point of issue of this new eruption.

FIG. 2.—Vesuvius as seen from San Georgio a Cremano before the eruption (commencement of July).

The first indication of the final splitting of the great cone was at midnight, when the crater became quiet. In half an hour (that is, on July 3 at 12.30 o'clock) when the guardian of the upper railway station of Mr. G. M. Cook's railroad, which is but a very short distance from the rift, was awakened by a strong shock of earthquake that produced some slight cracks in the masonry foundation of the building. The shocks, though slighter, continued during the night. At eight the stronger shocks were again repeated, and the activity, which had recommenced at the chimney, had again ceased. This was due to the filling of the fissure as it extended outwards by the lava, the level of the surface of which naturally sunk. When this takes place, support is removed from the inner sides of the chimney in the cone, which crumbles in and chokes the vent. The whole top of the mountain had by this time become fissured, in consequence of which, at nine o'clock, seven or eight large blocks of rock, besides a quantity of small ones, were detached from the top of the cone, crashed and ploughed down its side, leaving a scar described as looking like a mud stream, and marked by a number of pits at equal distances, due to the bounding of some of these boulders. This scar is seen in Fig. 3, close by the side of the right of the new lava stream. Mr. Treiber, Mr. Cook's engineer, calculates one of these blocks to be at least 20 c.m. The point of detachment and the resulting scar was by the side of the upper part of the new fissure, but a little to the south-west, and the traces left by the rolling masses are parallel to it.

At 10.18, the radial dyke reached the surface of the great cone and formed an eruptive mouth on a level with and to the north of the upper railway station, from which a copious outflow of lava took place, running down the cone, as seen in the figure below.

At 10.30, about 70 m. lower down, a fresh eruptive mouth was opened, and is well seen in Fig. 3, having an oblique

FIG. 3.—Vesuvius as seen on July 3, at 10 a.m.

crateriform appearance, as in the case of the upper one, and on other similar occasions a jet of steam, that constitutes the excavating agent, was converted into a blackish column by the lapilli, sand, and dust dislodged and carried up with it from the side of the mountain. There is certainly some discrepancy in Mr. Treiber's report, for Mrs. Guppy's sketch, made at ten o'clock, shows this lower *bocca* already in existence. Her sketch likewise exhibits the progress of truncation of the central eruptive cone by the formation within it of a crater. Such a crater is entirely due to the crumbling in of the edges and their fall down the chimney, as no explosions were going on by the top part of the main chimney. Lava continued to pour forth from the lower end of the lower crateret, and probably from a part of the radial fissure that reached the surface below it, but which of course is hidden by the flowing lava. The stream reached the bottom of the great cone at the junction of the Atrio del Cavallo and the Piano di Genista, and then extended towards the upper end of the ridge of the Lion's Paw, or I Canteroni, where was once the old Crocelle. Here it soon formed a fine stream 60 m. in breadth. Besides the two main craterets, already

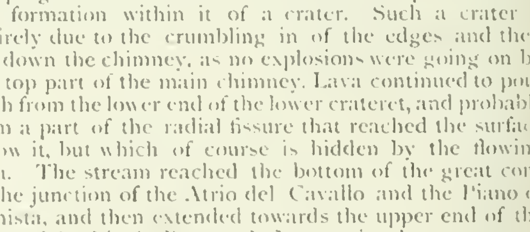

FIG. 4.—Vesuvius as seen on July 5, at 10 a.m.

described, two minor ones also were formed on the same line of rift.

On July 4, the craterets quieted down, little lava flowed, so that during twenty-four hours the face of the stream only advanced 12 m. This corresponded with a slight return of activity at the main chimney, so as to relieve the accumulating vapour tension of the lava below, which the mountain will not resist for long.

The ejections were, of course, of the *accessory* type (that is, not *essential* to the eruption, but simply the remnants of the crumbled-in portion of the eruptive cone. Each

[1] I have, moreover, to thank Mrs. Guppy for notes and sketches that, at considerable trouble, she has placed at my disposal. They are of much value, as she has observed and knows all the changes of the mountain during the many years she has resided in Naples.

puff had its characteristic black colour, due to the quantity of *accessory* sand and dust.

At 22 o'clock, the upper crateret gave out a little vapour and a little lava, but again became quiet. At 23 o'clock, the lower crateret showed new cracks around about it, with the escape of vapour.

During the night, between the 4th and 5th, the lava again increased, so that it is reported the next morning to be advancing at the rate of 25 m. per hour. It had turned to the west, and flowed down on the south side of the Lion's Paw, or the Observatory ridge, and had divided into two main streams, which subsequently subdivided into minor ones that radiated in different directions.

On July 5, the explosions at the central crater were powerful, so as to form from time to time pine-shaped vapour plumes over the volcano. At others, the vapour was bent over the Atrio by the sirocco wind, so as to spread a shower of dust and sand right across that depression. One of these is well indicated in Fig. 4.

So far no damage has been done except to a private carriage road that crosses the Piano di Ginista to the lower railway station. No cultivated land has been reached. The lava is, however, on a steep slope, and is flowing in the direction of the valley called the Cupa Pallarino, over the edge of which a magnificent cascade of incandescent rock was formed in 1872.

The eruption is quite identical in all its details with the usual antecedent ones, resulting from the formation and extension outwards of radial dykes. Many of such eruptions I have described in these pages and elsewhere, and fully explained their mechanism, production, growth and closure.

Three results may happen: (1) The radial sheet of rock may cool and seal the rift so that the volcano will soon return to the cone-forming stage, as seems to be indicated by the appearance of pasty lava cakes amongst the ejecta on July 5. (2) The fissure may enlarge and extend downward with the outflow of lava, as in 1872, with the formation of a much larger central crater. (3) It may follow the more usual course, as its immediate predecessor, and give issue to a small but almost continuous outflow of lava during months or years.

H. J. JOHNSTON-LAVIS.

P. L. CHEBYSHEV (TCHEBICHEFF).

THE death of Prof. Chebyshev has hardly been noticed in the English papers; and even in Russia, except for a short sketch in the University *Bulletin*, and in a speech of Prof. Markoff's with reference to him, which is reported in the *Bulletin de l'Académie impériale des Sciences de St. Pétersbourg*, no biographical notice has appeared of this celebrated mathematician.

Paphnyty Levovitch Chebyshev was born on May 14, 1821, at Akatovo, in the government of Kaluga; and after being educated privately, entered Moscow University; he completed the usual courses, and took his Bachelor degree. In 1846 he received his Master's degree at the same university for his "Essay on the elementary analysis of the theory of probability," and in the following year commenced a series of lectures as assistant lecturer in Petersburg University. He received the Doctor's degree in 1849 for his well-known "Theory of Comparison," which contained a model exposition of the formation of the theory of numbers, and clearly proved the strength of his mathematical genius. In 1852 Chebyshev was promoted to an extra professorship, and in 1860 to a regular professorship. During 1853-59 he was elected successively assistant, extra, and ordinary tutor in the Academy of Sciences. He remained a professor, doing active work of the most valuable kind, thirty-five years, during the course of which, at various times, he lectured on every branch of pure mathematics, and during one period—in 1849-51—on practical mechanics.

In his numerous writings Chebyshev left a very great deal to the reader's imagination, often giving deductions simply without proofs, but in his lectures he never left a point without the fullest explanation; and his lectures are distinguished not only for elegance and accuracy, but for their extraordinary simpleness; the already-mentioned "Theory of Comparison" may serve as a good example, as well as his proof of Bernoulli's theorem, which is now given in all works on the theory of probability.

The professorial services of Chebyshev had a great significance to the Petersburg University. He placed the teaching of mathematics on a firm basis, and formed an independent school of thought. All the present staff of mathematical teachers in the Petersburg University, except a very few of quite the youngest, are his pupils and follow in his footsteps. His moral influence did not, therefore, cease when he resigned his professorship in 1882. The Council of the University elected him an honorary member, and his pupils kept up the habit of going to him on certain days to have lively discussions on various scientific subjects, in which his indomitable energy acted on his hearers in the most animating manner. He was always to be found engaged either on some complicated calculation or on models of mechanism he had invented.

Everything Chebyshev did bore the impress of genius; he invented new methods for the solution of difficult problems, which had appeared and had remained unsolved; he suggested himself a series of most important problems, and worked at them till the end of his life. His very first writings on the theory of numbers, devoted to the problem of the inter-dependence of the prime numbers, and on limits, gave him a European reputation, and his succeeding investigations on irrational differentials, and maximal and minimal quantities, assured his position as the most original mathematician of the nineteenth century.

He died November 26, 1894; his works will shortly be republished by the Petersburg University.

NOTES.

As already briefly announced in these columns, the Institute of France will celebrate its centenary next October. The programme of the *fêtes* which have been organised in connection with that event has just been sent to the Members and Correspondants of the Institute, the intention being that the centenary shall be marked by a reunion of all the men of light and leading who belong to the Institute. On the afternoon of October 23, there will be a reception in the Palais de l'Institut of the Foreign Associates and Correspondants and of French Correspondants, and in the evening the Minister of Public Instruction will hold a reception. On October 24, a meeting will be held in the Great Hall of the Sorbonne, at which the President of the Republic will attend. Discourses will be delivered by the President of the Institute, the Minister of Public Instruction, and M. Jules Simon. A banquet, to which all the Associates and Correspondants are invited, will take place on the evening of the same day. On October 25, there will be a special performance at the Comédie Française, and a reception will be held by the French President. The celebration will be concluded on October 26, by a visit to the Château de Chantilly. It will be seen from this that the hundredth anniversary of the foundation of the Institute of France will be celebrated in a manner worthy of the high position which the Institute holds among the world's societies of science, art, and literature.

THE seventh session of the Australasian Association for the Advancement of Science will be held in Sydney, from January 3 to 10, 1897, under the presidency of Prof. A. Liversidge, F.R.S. The Presidents and Secretaries of the Sections are

as follows:—Astronomy, Mathematics, and Physics: President, Mr. R. L. J. Ellery, C.M.G., F.R.S.; Secretaries, Prof. R. Threlfall and Mr. J. Arthur Pollock. Chemistry: President, Mr. T. C. Cloud; Secretary, Mr. W. M. Hamlet. Geology and Mineralogy: President, Captain F. W. Hutton, F.R.S.; Secretaries, Prof. T. W. E. David and Mr. E. F. Pittman. Biology: President, Prof. T. J. Parker, F.R.S.; Secretaries, Prof. W. A. Haswell and Mr. J. H. Maiden. Geography: Secretary, Mr. H. S. W. Crummer. Ethnology and Anthropology: President, Mr. A. W. Howitt; Secretary, Dr. John Fraser. Economic Science and Agriculture: President, Mr. R. M. Johnston; Secretaries, Prof. Walter Scott and Mr. F. B. Guthrie. Engineering and Architecture: President, Mr. H. C. Stanley; Secretary, J. W. Grimshaw. Sanitary Science and Hygiene: President, Hon. Allan Campbell; Secretary, Dr. J. Ashburton Thompson. Mental Science and Education: President, Mr. John Shirley; Secretary, Prof. Francis Anderson. Communications and papers for the meeting, or inquiries, may be addressed to the Permanent Hon. Secretary, The Chemical Laboratory, The University, Sydney, N.S.W.

It is announced that the Hodgkins prize of ten thousand dollars has been awarded by the Smithsonian Institution, in equal proportions, to Lord Rayleigh and Prof. Ramsay, in recognition of their discovery of argon.

We regret to notice the death of Mr. Joseph Thomson, whose explorations in Africa have added so much to our knowledge of that continent. He was only thirty-six years of age.

Science announces the following appointments:—Prof. William J. Hussey, of Illinois, to succeed Prof. Barnard as Astronomer at the Lick Observatory; Dr. J. Allen Gilbert to be Assistant Professor of Psychology at the University of Iowa; Mr. J. H. Tyrrell to be Professor of Geology and Mineralogy in the University of Toronto.

Reuter's correspondent at Newfoundland, writing under date of July 23, says:—The steamer *Kite*, having on board the members of the Peary Relief Expedition, took her departure a few days ago for Bowdoin Bay, Inglefield Gulf. Her return can hardly be looked for before October 1.

Mr. Cecil H. Smith, of the Department of Greek and Roman Antiquities in the British Museum, has been appointed director of the British School at Athens for the next two years, in succession to Mr. Ernest Gardner, who has held the office since 1887. The Trustees of the British Museum have, with the concurrence of the Treasury, given Mr. Smith special leave of absence for the purpose.

The annual meeting of the Society of Chemical Industry was held at Yorkshire College, Leeds, last week. In his presidential address, Dr. T. E. Thorpe, F.R.S., described some of the important advances made in technological chemistry during recent years, and especially dwelt upon the methods used for the enrichment of coal gas; the manufacture of glycerine from waste soap lyes; the manufacture of edible fats; the improvements on the chemical side of photography; and the chemistry of textiles. The following new officers were elected:—President, Mr. Tyrer; Vice-Presidents, Mr. T. Fairley, Mr. Boverton Redwood, Sir H. E. Roscoe, Dr. T. E. Thorpe. Members of Council, Prof. Le Neve Foster, Mr. Douglas Herman, Mr. C. C. Hutchinson, Mr. Ivan Levinstein, Mr. J. S. McArthur, Sir Robert Pullar. Treasurer, Mr. E. Rider Cook. Foreign Secretary, Dr. Ludwig Mond. It was decided to hold the next annual meeting of the Society in London.

Bedford College (for Women) has taken what appears to us to be an important and commendable step in establishing a separate and scientific course of instruction in hygiene. This subject, which is becoming every day of more consideration, has generally been taught in a somewhat disconnected manner, as an adjunct to be attached anywhere, rather than as a distinct study; at Bedford College it is now to take its place as a special subject. Students will be required to devote themselves for a session or more solely to this and allied branches of science, namely, physiology, bacteriology, chemistry, and physics, practically as well as theoretically, and thus they will have the opportunity, by following a connected system of teaching, of really understanding the meaning and practical bearings of the subject. Many appointments as sanitary inspectors, health mistresses in schools, and teachers of hygiene, being now open to women, the subject seems to offer considerable inducement to those who have an aptitude and liking for scientific work, to devote themselves to this study.

Men of science often have occasion to regret that they do not live in the glorious age when tidal evolution shall have so reduced the spin of this world of ours that there will be forty-eight hours in a day. To be able to devote twice the present amount of time to observation would indeed be a boon to the busy investigator, and the man who shows how to do it, places his fellow workers under a deep obligation to him. Yet that is what Dr. Gowers, F.R.S., did in an inaugural address delivered before a general meeting of the Society of Medical Phonographers last week. Here is his argument: "Science rests on observation, which without immediate record is of little value; not only is memory inadequate, but record at once reveals unsuspected imperfections in observation. Compared with long hand, shorthand permits, in a given time, twice the amount of record, while leaving twice the time for observation." Shorthand requires no better recommendation than this to the notice of students of science, and we are glad to know that the Society of which Dr. Gowers is president, though only started last December, has now 165 members. In the daily work of the practitioner, which is peculiar in being a form of personal science, record is very important. For most practitioners, however, record is practically impossible in longhand, while shorthand offers them the desired means. But this is not only the case with medical men; it is always important that observations, however trivial or strange, should be committed to writing. We are, therefore, a little surprised that the Society should, so far as the name is concerned, be only one of Medical Phonographers. Its objects appear to be broad enough to justify the name being changed to the Society of Scientific Phonographers, and a further argument for the more comprehensive designation is that many scientific workers outside the ranks of the medical profession have already become members.

An interesting point in connection with the sand filtration of water has been recently brought to light by Dr. Kurth, of Bremen. It has frequently been pointed out that the thickness of the layer of fine sand in filtering beds cannot be reduced beyond certain limits without endangering the bacterial quality of the filtrate. Making more detailed examinations of the particular bacteria present in the effluent from a filter in which the depth of filtering material had been interfered with, Dr. Kurth found that the rise in the number of bacteria was almost entirely due to the presence in large quantity of one particular microbe, of which, however, no trace could be found in the raw water with which the filter was being fed. On one occasion there were as many as 900 in 1 c.c. present of this special microbe, whilst all the bacteria together in the raw water did not amount to more than 700 in 1 c.c. In this instance, therefore, the objectionable rise in the number of bacteria present in the filtrate did not necessarily indicate that the efficiency of the filter in dealing with the raw water was in fault, but rather that the disturbance

of the sand had dislodged certain microbes present in the filtering material. It would appear, therefore, of interest to obtain in cases where the filtrate is unsatisfactory some particulars of the microbes present in the effluent, and determine in what relation they stand to the raw water microbes.

The question of the audibility of fog-horn signals at sea seems destined to occupy a great deal of attention in naval circles. Some time ago we gave a description of the American experiments, which went to prove that round each siren there is a zone, about $1\frac{1}{2}$ nautical miles broad, within which fog-signals cannot be heard, although they are distinctly heard outside that zone. These observations cannot now be treated with the incredulity they at first met with, since other experiments have confirmed them. A series of such experiments are described in *Hansa*. In one of these, the vessel steamed with the wind straight towards the light-ship from a distance of $4\frac{1}{2}$ nautical miles. At a distance of $2\frac{3}{4}$ miles the sound became faintly audible, and suddenly increased in loudness at $2\frac{1}{2}$ miles, retaining the same intensity up to two miles distance. From $1\frac{3}{4}$ to $1\frac{1}{2}$ miles the note was scarcely audible, but then it immediately increased to such an extent that it appeared to originate in the immediate neighbourhood of the vessel. The steamer at this point reversed its course, and the fluctuation over this part of the course was found to be the same, except that it was even more strongly marked. Reversing again, the vessel steamed over this distance a third time, and again the sound disappeared at $1\frac{1}{2}$ miles and reappeared again, so loud that it sounded as if the fog-horn was only two cables' lengths off. Then, at half a mile, the sound disappeared entirely, to reappear at quarter of a mile from the light-ship, after which it gradually and steadily increased in intensity until the latter was reached. It is time that this question, which is of great practical importance, should be systematically investigated.

The second annual report of the Iowa Geological Survey, dealing with the work done during 1893, has just come to hand. The Survey was organised just three years ago, and it has carried out some very valuable investigations during its comparatively short existence. The coal deposits of Iowa have received special attention since the organisation of the Survey, and one volume descriptive of them was issued last year. But these deposits are far too extensive to be discussed in a single volume. We have it on the authority of Dr. C. R. Keyes, the Assistant State Geologist, that the area of the coal measures in Iowa is somewhat over twenty thousand square miles, and that isolated carboniferous outliers, and the region bordering the productive coal measures, which must be gone over in tracing the limits of the formation, occupy fully five thousand square miles or more. With reference to the beds of gypsum at Fort Dodge, Dr. Keyes says the area covered by the gypsum contains, approximately, twenty-seven square miles, and that, at the lowest estimate, the mass of gypsum which is found available in the region is not less than sixty millions of tons. Much valuable data with reference to these deposits are given in the report, and also information in regard to the building stones, clays, and other useful mineral substances in Iowa. Though the Survey has primarily a utilitarian point of view, it is clear from the report that the more scientific side of geology is not neglected. Prof. W. H. Norton contributes to the report a paper on the thickness of the Palæozoic strata in North-Western Iowa, based upon records of a number of borings for artesian and other deep wells. He also gives the results of a study of Devonian and Carboniferous outliers in Eastern Iowa. The report is illustrated by thirty-four figures in the text, and thirty-six plates; the most striking of the latter belong to a paper by Dr. Keyes, on glacial scorings in Iowa. Two new localities showing exceptionally fine effects of glacial action were found near the city of Burlington in 1893. One of them is near Kingston, on the top of a bluff overlooking the Mississippi river, and judging from the reproduction of a photograph, it furnishes a very remarkable example of a glaciated surface. Prof. Calvin, the State Geologist, is to be congratulated upon the work carried on under his direction. The Survey has lately lost Dr. Keyes, who has become State Geologist of Missouri, his place being filled by Mr. H. F. Bain.

The fifty-sixth annual meeting of the Royal Botanic Society will be held in the Gardens, Regent's Park, on Saturday afternoon next, the 10th inst., at one o'clock.

A dainty catalogue, in which many rare and valuable geographical works are described, has been issued by Mr. Bernard Quaritch. The catalogue should be seen by all interested in geographical literature.

We learn from the *Journal of Botany* that the herbarium of the British Museum has recently acquired a very fine collection of Hepaticæ made by Herr F. Stephani. It numbers about 10,000 specimens, and includes types of 1100 new species described by Herr Stephani.

The *Proceedings* of the Liverpool Naturalists' Field Club for 1894 contain a record of a large amount of scientific work done in the way of botanical excursions in Lancashire, Cheshire, and North Wales; a list of carboniferous fossils found within twenty miles of Liverpool; and reports of papers read at the evening meetings. The total number of animals and plants that has been recorded as occurring in the district, both living and extinct, is given as 5735.

The August number of the *Quarterly Journal of the Geological Society* contains a paper, by Dr. J. W. Gregory, on the Palæontology and Physical Geology of the West Indies. Among the other papers we notice the following:—Prof. J. B. Harrison and Mr. A. J. Jukes-Brown, on the chemical composition of oceanic deposits; Mr. H. M. Bernard, on the systematic position of the Trilobites; Prof. W. J. Sollas, on the mode of flow of a viscous fluid; Dr. C. S. Du Riche Preller, on fluvio-glacial and inter-glacial deposits in Switzerland; and Mr. E. T. Newton, on fossil human remains from Palæolithic gravels at Galley Hill, Kent.

The Royal College of Belen, Havana, has just published its magnetical and meteorological observations for the year 1890. This institution has regularly issued reports since 1862, and the continuous instrumental curves, which accompany the tables, have furnished valuable information for the investigation of West India hurricanes. Since 1872, one of the late Padre Secchi's well-known and expensive meteorographs has been regularly at work at Havana, and is said to give very satisfactory results. We note that an attempt is made each month to connect the magnetical with the atmospherical disturbances.

We have received from the Jesuit College of Oña, province of Burgos, a pamphlet containing meteorological observations made twice daily, with monthly and yearly results for the years 1883–1894. The Observatory is 1900 feet above sea-level, and is rather sheltered; but the summary of the climate of that part of Spain by Prof. Valladares, and the observations of cirrus clouds and their connection with atmospheric disturbances, are valuable contributions to meteorological science. During the twelve years in question, the extreme shade temperatures varied from 1°·3 to 100°, the annual mean being 51°·8, and the average yearly rainfall was 22 inches.

M. Casimir de Candolle contributes to the *Archives des Sciences Physiques et Naturelles* an important paper on the latent life of seeds. From a series of experiments, chiefly on seeds of wheat, oat, and fennel, he concludes that dormant seeds pass through a period of completely suspended animation.

in which all the functions of the protoplasm are quiescent, but from which they revive when again placed in conditions suitable for germination. The immunity from injury appears to depend on the protoplasm of the seed passing into a completely inert state, in which it is incapable of either respiring or assimilating, before exposure to the unfavourable conditions. The period of suspended animation may extend over an indefinite time, probably through a long series of years, and the seeds may during this period be subjected to very low temperatures without destroying their vitality. Those above mentioned were exposed, in a refrigerator, as many as 118 times in succession, to a sudden cooling to temperatures varying between −30 and −53° C., without injurious effects. On the other hand, seeds of the sensitive plant and of *Lobelia Erinus* succumbed, for the most part, to similar treatment. These statements have an important bearing on the question of the retention of their vitality by buried seeds.

The additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Herman Schlesenger; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Miss Folhurst; a Macaque Monkey (*Macacus cynomolgus*) from India, three Slow Lorises (*Nycticebus tardigradus*) from Sumatra, presented by Mr. Stanley S. Flower; a Geoffroy's Marmoset (*Midas geoffroii*) from Panama, presented by Miss Mina Sangiorgi; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mdlle. Eugénie Grobel; a Barbary Ape (*Macacus innuus*) from North Africa, presented by Mr. Edwin Fletcher; two Crested Porcupines (*Hystrix cristata*), two Cape Zorillas (*Ictonyx zorilla*) from South Africa, presented by Mr. J. E. Matcham; a Ducorp's Cockatoo (*Cacatua ducorpsi*) from the Solomon Islands, presented by Mrs. Dexter; a Nightjar (*Caprimulgus europaeus*), European, presented by Mr. T. West Carnie; two Robben Island Snakes (*Coronella phocarum*) from South Africa, presented by Mr. Barry McMillam; —— Chameleon (*Chamaeleon basiliscus*) from Egypt, presented by Mr. J. Buchanan; a Brown Capuchin (*Cebus fatuellus*) from Guiana, a Black-backed Jackal (*Canis mesomelas*) from South Africa, six Ring-tailed Coatis (*Nasua rufa*) from South America, deposited; a Red River Hog (*Potamochoerus penicillatus*) from West Africa, a Sooty Phalanger (*Phalangista fuliginosa*) from Australia; a De Filippi's Meadow Starling (*Sturnella defilippi*) from La Plata, purchased; two Mandarin Ducks (*Aex galericulata*), seven Summer Ducks (*Aex sponsa*), three Chilian Pintails (*Dafila spinicauda*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Rotation of Venus.—Notwithstanding the persistence with which the planet Venus has been telescopically observed, the period of rotation is still undetermined with anything like certainty. Schroter believed the time of rotation to be 23h. 21m.; and this period, or thereabouts, was pretty generally adopted until the announcement by Schiaparelli, in 1890, that the time of rotation was probably equal to that of the planet's revolution round the sun, that is, about 225 days. This conclusion was based on the rigidity of the markings at different hours of the day and for weeks together. Observations by M. Perrotin and Dr. Terby tend to strengthen the conclusion arrived at by Schiaparelli. On the other hand, M. Niesten observed the planet between 1881 and 1890, and found that a period of 23 hours satisfied his observations; while M. Trouvelot, from nearly twenty years' work, concludes that the rotation period was about 24 hours. In this divided state of opinion, therefore, it is evident that much remains to be done before any satisfactory conclusion can be drawn.

During the present year, Mr. Brenner, of the Manora Observatory, has observed the planet as frequently as possible since April 17 (*Ast. Nach.* 3300). His first observations of a bright and a dark spot near the north pole led him to agree with Schiaparelli, but further observations have changed his opinion, and he now believes the period to be about 24 hours. On July 2 he announced that a marking near the southern cusp had been visible since June 9, but became invisible about 4 p.m. each day, while a well-marked streak appeared about 8 p.m. Other marks also appeared and disappeared in a manner inconsistent with a rotation period of more than 24 hours. One of the most important of the markings, though noted quite independently, appears to be identical with one observed by Mr. Stanley Williams eleven years ago: in a communication to Mr. Brenner, Mr. Williams states: "In 1884 I managed to secure about one hundred sketches of the markings on Venus. These mostly favour a rotation of about 24 hours; but there was one strongly-marked indentation near the southern horn, which remained visible continuously for about a month. It was prolonged on the disc by a narrow and unusually dark and definite streak (for Venus)." Mr. Brenner has since claimed to have proved with certainty that Venus rotates in about 24 hours: some of the markings return regularly at the same hour of the day, and are invisible at other times, when the definition is equally good; and it is even possible to observe the appearance and advancing of the most conspicuous streak.

Geodetical Observations.—Dr. Geelmuyden, of Christiania, has recently published the results of a comparison between the astronomical and geodetical determinations made in the course of a triangulation of Norway. The stations selected for observation lie between 59 and 64° lat., and the astronomical work connected with the investigation was conducted under the direction of the late Prof. Fearnley, extending as far back as 1868. The observations refer to measurements made at eleven stations, of which nine have both the azimuth and latitude determined, and two the difference of longitude.

As origin for the geodetical survey, the geographical coordinates of Dragonkollen, a station on the Swedish border, have been chosen, partly because its position is particularly well determined, but principally on the ground that its situation points to the existence of a very small local attraction. Assuming that for this station a vertical line coincides with the normal of Bessel's ellipsoid, Dr. Geelmuyden has computed, with the data already collected in the course of the geodetic survey, the deviations of the plumb-line for the other stations, in which both the azimuth and the latitude have been determined. The results are shown in the following table:

Station.	Difference of azimuth.	Difference of latitude.	Deviation of vertical.
Jonsknuden	+ 8·55	− 1·31	5·17
Gausta	− 6·23	—	—
Husbergöen	− 0·72	+ 0·54	0·68
Christiania	− 3·87	+ 1·79	2·87
Högevarde	− 13·00		—
Hostbjörkampen	+ 6·40	+ 4·68	5·88
Næverfjeld	+ 4·49	+ 6·62	7·06
Gien	− 10·72	− 2·65	6·20
Graakallen	− 7·71	− 6·98	7·98
Norberghaug	− 6·70	+ 0·67	3·36

The deviations of the plumb-line here shown, agree on the whole with what might be expected from the conformation of the surface and the contiguity of neighbouring mountains. For example, the westerly deviation of Gien can be explained by the attraction of Dovrefjeld. An exception is, however, met in the case of Norberghaug, where an easterly rather than a westerly deviation would have been expected. A map is attached, in which is shown both the position of the several stations and the direction of the deviation of the plumb-line.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual summer meeting of the Institution of Mechanical Engineers was held in Glasgow last week, under the chairmanship of the President of the Institution, Prof. Alexander B. W. Kennedy, F.R.S. A strong local committee had been organised under the chairmanship of Sir Renny Watson, Prof.

Archibald Barr being Secretary, and very complete arrangements had been made for the instruction and entertainment of members taking part in the meeting. In a great engineering centre there can be no lack of objects of interest to afford excursions for a meeting of this Institution, and the organising committee had taken full advantage of the facilities put at their disposal by owners of works who had liberally thrown them open to members.

The meeting commenced on Tuesday, July 30, and was brought to a conclusion on the Friday following. The mornings of the two first days were devoted to the reading of papers, of which the following is a list:—

Hydraulic stoking machinery and labour-saving appliances in modern gas works, by Andrew S. Biggart.

Notes on modern steel-work machinery, by James Riley.

Recent engineering improvements of the Clyde Navigation, by James Deas, Engineer of the Clyde Navigation.

Notes on hydraulic power supply in towns: Glasgow, Manchester, Buenos Ayres, &c., by Edward B. Ellington.

Papers on telemeters and range-finders for naval and other purposes, by Profs. Barr and Stroud, and on the electric lighting of Edinburgh, by Henry R. J. Burstall, were also on the agenda, but had to be adjourned until the next meeting.

On members assembling in the Institute of Fine Arts, they were welcomed by the Lord Provost of Glasgow, Sir James Bell, and the usual formal business having been disposed of, the first paper was taken, namely, that of Mr. Biggart, on gas works machinery. In this the author described an extensive hydraulic plant which has recently been laid down at the Dawsholm Gas Works in Glasgow. The apparatus is designed to supersede hand labour in the charging of retorts, and clearing them of the residual coke when the gas has been abstracted from the fuel. The usual method of performing these operations by hand must be known to most people. The coal having been broken to suitable size by hand, is placed in the retort by means of a long half-round scoop or trough. This is pushed into the retort and then turned over, the coal then being spilled and spread evenly throughout the length of the retort. This is very laborious work, and moreover the smoke and dust accompanying it are very injurious. It is, however, less trying than the discharging of the retorts, an operation which consists of raking out a mass of coke almost at a white heat. It will be easily understood, even by those not personally acquainted with gas works, that labour of this nature does not tend to the advancement of the labourer, for though good wages are paid they are apt to be spent in ways not all that could be desired. The introduction of machinery to supersede this somewhat demoralising work is therefore a distinct boon to the workman as well as the proprietors of gas works, and thus, indirectly, the users of gas; in fact, it is the oft-told tale of intelligent work being required to produce machines which take the place of the unthinking labourer. That is very nearly the whole history of the elevation of the working classes. In the machinery described by Mr. Biggart, and illustrated by wall-cartoons displayed at the meeting, the coal is broken by a machine having rolls with powerful steel claws which draw in the coal and break it to pieces of the required size. The coal is conveyed by means of buckets travelling on chains; these scoop it up and take it to the machine or to the required spot after it is broken. The charging machine consists first of a steel frame mounted on a carriage which runs on rails laid on the platform in front of the battery of retorts. Attached to the frame is a hopper, and from this a given quantity of coal is allowed to fall in front of a "pusher-plate." The function of the latter is to thrust the coal into the retort, the necessary forward motion being obtained by means of a hydraulic ram. A second ram is used to withdraw the pusher. About six or seven pushes are required to place the coal in a retort, the quantity that has to be placed at the far end naturally going in first. The arrangement of the mechanism is such that the coal is practically level in the retort, a fact which the gas manager looks on as important. There are many very ingenious devices incorporated in the design of this machine, which we have described in so elementary a manner, but to make them clear we should require somewhat elaborate illustrations. All charging operations are performed by means of a single lever. Having charged one retort, the machine is run along the lines of rail to the next retort, and so on through the whole range.

Having described the main outline of the charging machine, the action of the drawing machine hardly needs explanation, the two being so like in principle. In both the mechanism for raising the pusher or rake, respectively from the coal or coke so as to clear them, is very ingeniously devised, compared to hand labour. The saving in time and labour is considerable, as the machine will charge forty-eight retorts in an hour under favourable conditions. Not half the number of men are required in the retort-house; and it is said that the saving which this represents, averages about a shilling per ton of coal carbonised. As, roughly, about 8,000,000 tons of coal are annually used for gas-making in this country, it will be seen that the universal use of these machines should lead to a saving of £400,000 every year, to say nothing of relieving the working classes of exhausting and by no means elevating labour. It is, however, worthy of note, as indicative of the spirit of the age, that it was strikes, or the fear of strikes, that led to the more general introduction of these labour-saving appliances.

In the long discussion that followed the reading of the paper, the most notable point was the testimony of experienced persons as to the success of these machines.

Mr. James Riley's paper, on modern steel works machinery, was a valuable contribution to the published knowledge on this subject. Mr. Riley has taken a prominent position in the manufacture of mild steel from the time the material was introduced commercially, and he therefore speaks with authority. He was connected with the now almost classic Landore Works under Sir William Siemens, but it was as head of the Steel Company of Scotland that he made his name most widely known: indeed, there is no one to whom naval architects and ship constructors owe more than to the author of the paper for what has been done in the development of the steel-plate industry. Mr. Riley has recently found a new field for his energies, and it was largely in the description of the plant which he has been fitting up, that his paper dealt.

Some of the most impressive examples of the mechanical engineer's art are to be found in the modern steel works of this country. Massive cogging-mills, which will roll down an ingot of ten tons of steel, almost at a white heat, into slabs: hydraulic shears which crop off the ends of these slabs, cutting through a thickness of 12 inches and a width of 5 feet of glowing steel; the enormously powerful hydraulic forging presses—the casting for the cylinder alone, in an instance mentioned by Mr. Riley, weighing 64 tons; the plate mills, rail mills, hot saws, the live rollers and hydraulic turning gear, which deal with many ton ingots of steel as if they were but playthings; all these form an exemplification of artificial force hardly surpassed. The paper in question gave descriptions in detail of the most recent examples of these machines, which it would be of interest to repeat; but the difficulty of making the forms of construction clear without the diagrams shown on the walls, will compel us again to confine ourselves to mere outline. In a cogging mill described and illustrated, slabs up to 60 inches wide could be produced, and these are rolled on their edges by vertical rolls, the ordinary horizontal rolls being used for rolling on the flat. Ingots and slabs are taken to and from the mill by special carriages actuated by hydraulic rams. Hydraulic slab shears, described in the paper, have a centre cylinder of 31 inches in diameter, and two side ones 22 inches each; the work being held down by hydraulic power whilst being sheared. The accumulator pressure is one ton per square inch. The table has two hydraulic cylinders, by which it is raised or lowered. Steam slab cutting shears and plate mills are also described. The author advocates the use of three-high plate mills in place of the more usual reversing mill. A three-high mill runs continuously, the work being passed forward between the bottom and middle roll, and back between the top and middle roll. The frequent reversing of the engine driving the ro thus done away with, is naturally a source of loss. Hydraulic power has also been adopted for working plate shears, the mechanism employed for actuating the blades being of the nature of a toggle arm worked from a crank shaft by levers.

A long discussion followed the reading of this paper, in which the desirability of rolling plates from the ingot, without previous cogging, was considered very fully. In America this practice is largely, indeed all but universally, followed; but the general opinion of the high authorities who spoke, appeared to be that in England, owing to the diversity of sizes of plates required, cogging into slabs was a necessary part of plate rolling. It is possible, however, that by properly apportioning mills to the description of work required, the intermediate process may in time become less universal in this

country. That, however, remains to be seen, and one must remember how difficult it is to shake trade customs, however much they may stand in the way of advancement in manufacturing processes.

Mr. Deas' paper on Clyde navigation improvements was another excellent contribution to the proceedings of the Institution, although perhaps rather of the nature of a civil than a mechanical engineering paper. We use the term "civil engineering" in its restricted but more generally accepted sense. The Clyde is probably the most artificial tidal river in the world. What man has done for the Clyde, and what the Clyde has done for Glasgow, every one has heard. Mr. Deas carries the details of the narrative a step further, showing how he built up good and enduring quay walls where the nature of the ground rendered the task one of the greatest difficulty. The most striking feature was the series of hollow concrete cylinders, sunk into the natural sand or gravel to form a foundation for the quay walls. The method of sinking was ingenious, and to those interested in these matters a perusal of the paper will be of great interest, both in regard to this and many other points.

Mr. Ellington's paper was one of great interest, as, indeed, were all the memoirs read at this meeting. The author has taken the foremost position in the introduction of the distribution of hydraulic power from a central station. The first example on a large scale was the installation at Hull, which was laid down in 1877. This was followed, after an interval of seven years, by the London scheme, which has now reached large dimensions, not far from ten million gallons of water being pumped per week at a pressure of 750 lbs. to the square inch: the mains extending over the most important parts of the metropolis. Since then the system has been applied in Liverpool, Melbourne, Birmingham, Sydney, and Antwerp; the latter city using over three million gallons per week. The latest examples are Manchester and Glasgow, where the pressure has been increased to 1120 lbs. to the square inch. It was the Glasgow scheme that Mr. Ellington chiefly described. These works have been carried out under the supervision of Mr. Corbet Woodall, acting for the Corporation. The engine-house is laid out to contain six sets of triple compound engines of 200-horse power each. There are two accumulators having rams 18 inches in diameter, and 23 feet stroke; each is loaded to 127 tons. The capacity is 57,500 gallons per hour at the standard pressure of 1120 lbs. to the square inch. The water supply is taken from the Corporation mains; in London Thames water is used. The mains are 7 inches in diameter, there being gutta-percha packing rings at the joints.

Speaking of the efficiency of the system, the author founded his remarks chiefly on his experience in London, and it was found that the average for ten years was 0·9243. The efficiency is determined by the fraction representing the ratio of the quantity of water registered by consumers' meters to the quantity pumped at the central stations. In Liverpool a still better coefficient is obtained, the efficiency being 0·9555. A Parkinson meter is used by the author; this is very like a gas meter. The Kent positive low-pressure meter is largely used in London.

Perhaps the most interesting part of Mr. Ellington's paper was that in which he compared the cost of hydraulic power supply and electric supply. The results were largely in favour of the water system, and were certainly somewhat surprising to many. In making this comparison data were taken from the records of the London Hydraulic Power Company and of the Westminster Electric Supply Corporation. In making the comparison 1000 gallons of water at 750 lbs. per square inch is taken as equivalent to 6·518 Board of Trade units of electricity. The analysis showed that the station cost of hydraulic power is 5·172*d.* per thousand gallons pumped at a pressure of 750 lbs. per square inch. The corresponding cost of an equivalent amount of electric energy, reduced to the same hydraulic standard, is 9·014*d.* per thousand gallons; on an electrical standard of Board of Trade units of 0·703*d.* and 1·383*d.* for hydraulic and electrical energy respectively. It was a curious coincidence that, in making this comparison, the capital outlay, output, quantity sold, and average price obtained were nearly the same; it was only in cost of production that the divergence was remarkable. A further point that came out in the discussion was that the dividends paid by the two companies respectively were not greatly different. The author could come to no other conclusion on the figures than that, from some cause not hitherto explained, hydraulic power is much less costly to produce than electricity. Prof. Kennedy, who occupied the chair, and who is so largely responsible for the distribution of electrical energy, could find no fault with Mr. Ellington's figures; but we believe the matter is likely to become the subject of further investigation.

We do not propose dealing with the many excursions that were made, and which included visits to a large number of shipyards, engine works, iron and steel works, as well as the large Corporation undertakings, such as the gas and water works. To describe these at all adequately would require a volume rather than an article. It will suffice to say here that these excursions were well attended, and the meeting was highly successful generally.

THE INTERNATIONAL GEOGRAPHICAL CONGRESS.

THE closing meeting of the International Geographical Congress took place on Saturday morning (August 3), and there seemed to be no dissentients from the opinion that in all its departments the Congress has been a great success. In particular, the meeting is to be congratulated on accomplishing much important work, and combining therewith a large amount of entertainment and social intercourse, without unduly taxing the energies of its members. While there was no reason to expect, in a scientific body like the Congress, any serious complication of interests, it is specially satisfactory to recognise the spirit which showed itself in all the sittings from day to day, and found its most definite expression in the graceful and courteous speech in which General Greely seconded the proposal that the Congress accept the invitation of the German delegates to hold the next meeting in Berlin. The Congress has not as yet met in Germany, and it was felt that a large number of members would have great difficulty in attending a meeting at Washington, although a visit to the United States offered many inducements to accept the cordial invitation which came from that country.

At the close of its proceedings the Congress gave deliverance on a number of important questions which we may take as representing the general views of geographical experts on matters of special moment in that branch of science. With regard to Africa it was agreed that it is desirable to bring to the notice of the Geographical Societies interested in Africa the advantages to be gained:

(1) By the execution of accurate topographical surveys, based on a sufficient triangulation, of the districts in Africa suitable for colonisation by Europeans.

(2) By encouraging travellers to sketch areas rather than mere routes.

(3) By the formation and publication of a list of all the places in unsurveyed Africa, which have been accurately determined by astronomical observations, with explanations of the methods employed.

(4) By the accurate determination of the position of many of the most important places in unsurveyed Africa, for which operation the lines of telegraph already erected, or in course of erection, afford so great facilities.

Resolutions were passed as to the collection and cataloguing of cartographic materials, and urging that all maps should bear the date of their publication, and the report of an influential commission appointed at Berne to consider a proposed map of the world on a scale of 1 : 1,000,000 was adopted in a form embodying a resolution that:

(1) The Commission has received the Report of the Berne Committee, and feels grateful for the work done by it.

(2) The Commission declares that the production of a map of the earth to be exceedingly desirable.

(3) A scale of 1 : 1,000,000 is recommended as being more especially suited for that purpose.

(4) The Commission recommends that each sheet of the map be bounded by arcs of parallels and of meridians. A poly-conical projection is the only one which is deserving of consideration. Each sheet of the map is to embrace 4 degrees of latitude and 6 degrees of longitude, up to 60 degrees north, and 12 degrees of longitude beyond that parallel.

(5) The Commission recommends unanimously that the meridian of Greenwich and the metre be accepted for this map.

(6) The Commission recommends governments, institutions, and societies, who may publish maps, to accept the scale recommended.

(7) The Commission lays down its mandate, and recommends

that the Executive Committee of the Congress be charged with the duty of carrying on its work, and be authorised to co-opt for this purpose scientific men representing various countries.

Support was given to the proposal for further international surveys in the North Atlantic, the North Sea, and the Baltic, by the adoption of a resolution, drawn up by a special Committee—"That the Congress recognises the scientific and economic importance of the results of recent research in the Baltic, the North Sea, and the North Atlantic, especially with regard to fishing interests, and records its opinion that the survey of these areas should be continued and extended by the co-operation of the different nationalities concerned on the lines of the scheme presented to the Congress by Prof. Pettersson."

The recommendation of the Education Committee was adopted, to the effect that—"The attention of this International Congress having been drawn by the British members to the educational efforts being made by the British Geographical Societies, the Congress desires to express its hearty sympathy with such efforts, and to place on record its opinion that in every country provision should be made for higher education in geography, either in the universities or otherwise."

Other resolutions were also carried, expressing the approval of the principle of State printed registration of literature, as the true foundation of national and international bibliography, urging the need of some agreement as to the writing of place-names, and acknowledging the scientific necessity of an international system of stations for the observation of earthquakes.

Besides the above, a number of resolutions were adopted in the course of the daily deliberations, of which the following is, perhaps, the most important of all the decisions of the Congress.

The resolution refers to the Exploration of the Antarctic regions, concerning which the Congress recorded its opinion that this is the greatest piece of geographical exploration still to be undertaken, and in view of the additions to knowledge in almost every branch of science which would result from such a scientific exploration, the Congress recommended that the several scientific societies throughout the world should urge in whatever way seemed to them most effective, that this work shall be undertaken before the close of the century.

The following is a summary of the proceedings of the Congress during the week. Previous meetings were reported in our last issue.

The general session on Monday (July 29) opened with a paper on Antarctic Exploration by Geheimrath Prof. Dr. G. Neumayer, and a discussion followed, in which the President, Sir Joseph Hooker—the only survivor of Sir James Clark Ross's Antarctic Expedition of 1843—Dr. John Murray, Sir George Baden-Powell, Mr. Arundell, M. de Lapparent, General Greely, and Prof. Guido Cora took part; and a committee was appointed to draft the resolution already quoted. The Congress then turned its attention to the Arctic regions, papers being presented by Admiral A. H. Markham, General Greely, Herr S. A. Andrée, and M. E. Payart. Herr Andrée's project for reaching the North Pole by means of balloons was somewhat severely criticised, but the author was confident of being able to meet all the difficulties suggested, and announced that he had already obtained the funds necessary for his expedition. A paper on Russian researches on a sea route to Siberia was afterwards read by Lieut.-Colonel de Shokalsky.

In the afternoon, General Annenkoff and Mr. J. Y. Buchanan presided over Section B, which dealt with papers relating to physical geography. M. le Comte de Bizemont presented a paper by M. G. Lennier on the modifications of the coasts of Normandy, and Prince Roland Bonaparte gave an account of researches on the periodic variations in French glaciers. After these were discussed, papers on the decimal division of time and angles, on the centesimal division of the right angle, on standard time, and on a system of symbolic hour zones, were read by M. le Dr. J. de Rey Pailhade, M. Louis Fabry (presented by M. Jacques Léotard), M. Bouthillier de Beaumont (presented by M. le Comte de Bizemont), and Prof. d'Italo Frassi, and a further discussion followed.

Section C, presided over by M. le Colonel Bassot and Colonel Sir Henry Thuillier, concerned itself with geodesy, and important papers were read on the geodetic operations of the Indian Survey, by General J. T. Walker, C.B., F.R.S., late Surveyor-General of India; the desirability of a geodetic connection between the surveys of Russia and India, by Colonel T. H. Holdich, C.B. (read by Colonel Sir John Ardagh); the general levelling of France, by M. Charles Lallemand, Directeur du Service du nivellement général; the rise and progress of cartography in the Colony of the Cape of Good Hope, by A. de Smidt, late Surveyor-General of that colony; and on the geodetic survey of South Africa, by Dr. David Gill, F.R.S., Astronomer-General for Cape of Good Hope (communicated by Mr. A. de Smidt).

In the course of discussion the need of surveys of the Nile Valley in connection with the South African triangulation was emphasised.

On Tuesday, July 30, the general meeting was chiefly occupied with reports, and the discussion of resolutions already referred to. Section B was devoted to oceanography, under the presidency of Dr. John Murray. Mr. J. Y. Buchanan gave a retrospect of oceanography during the last twenty years, and read a paper, by the Prince of Monaco, on the work of the yacht *Princess Alice*. A paper on ocean currents and the methods of their observation, by Captain A. S. Thomson, was laid on the table; and Prof. W. Libbey, of Princeton, gave an account of some valuable researches on the relations of the Gulf Stream and the Labrador current. Prof. Libbey's investigations have afforded some remarkable results bearing on the migrations of fish on the eastern seaboard of the United States, and they form an interesting contribution to the study of certain problems in marine zoology. A paper by Prof. J. Thoulet, suggesting that geographical societies in towns situated near the coast should interest themselves in the oceanography of neighbouring seas, was laid on the table.

Section C, presided over by Prof. H. Cordier and Prof. J. J. Rein, discussed geographical orthography and definitions. Papers were read on the orthography of place-names by Mr. G. G. Chisholm; on geographical place-names in Europe and the East, by Dr. James Burgess; and on the transliteration and pronunciation of place-names, by Dr. Giuseppe Ricchieri.

Popular interest in the Congress probably reached its highest point at the general meeting on Wednesday (July 31), when the proceedings related exclusively to Africa and its development. Sir John Kirk read a paper on the suitability of tropical Africa for development by white races or under their superintendence, dealing with the possibilities of colonisation proper, the establishment of European settlements in places permitting of temporary residence, and the means whereby the native races may themselves be taught to aid in the development of the country. Count von Pfeil laid down the conditions of success in colonising tropical Africa, which he said were chiefly a thorough knowledge of the character of the country it was proposed to colonise, of tropical hygiene, and of the art of making the native take an active share in the work. Mr. Silva White's paper dealt with the problem from various points of view, the author concluding that tropical Africa is on the whole unsuitable for European colonisation, and that it is capable of only a limited degree of development as compared with other and still undeveloped regions of the world. Mr. H. M. Stanley, Mr. E. G. Ravenstein, M. Lionel Décle, and Slatin Pasha also presented communications to the meeting, and a discussion followed. General Chapman read a paper on the mapping of Africa, and a proposal was referred to a committee whose report includes the resolution given above. A paper on a crestographic map of Africa was read by Mr. Silva White, and another by M. Victor de Ternant, on French Africa, was laid on the table.

Only one of the sections met (Section C). The Presidents were Dr. A. Gregoriev and Prof. Libbey. Oceanographical papers were communicated by Prof. Otto Pettersson and Mr. H. N. Dickson, dealing with recent research in the North Sea. Prof. Pettersson submitted a scheme for an extension of the same work, and a committee was appointed to draw up the resolution afterwards adopted by the Congress. A paper on limnology as a branch of geography was then read by Prof. Forel, and after remarks by Prof. Anuchin, Prof. Halbfass, Prof. Penck, Prof. Libbey, and M. de Krapotkine, Dr. H. R. Mill asked that his paper on "Limnology in the British Islands" be held as read. Señor F. A. Pezet gave an account of the counter-current "El Niño" on the coast of Northern Peru.

The general meeting of Thursday (August 1) opened with a return to the subject of Antarctic exploration. Mr. C. E. Borchgrevink, who had been unable to reach London in time for the meeting on Monday, read a paper on his voyage in the *Antarctic* to Victoria Land. Prof. C. M.

Kan read a paper on Western New Guinea, and future exploration in Australia was discussed by Mr. David Lindsay. A memoir on the Niger lakes, by M. Paul Vuillot, was laid on the table, and one on explorations in Madagascar, by M. E. F. Gautier, was communicated in abstract. In the absence of M. Maistre, who was to have read a paper on the hydrographic system of the Shari and Logone, Señor Don Torres Campos gave an account of the climatology of the Portuguese and Spanish colonies on the west coast of Africa.

Section B—Presidents, M. Levasseur and Mr. Ravenstein—received the following papers:—On the construction of a terrestrial globe on the scale of 1 : 100,000, by Prof. E. Reclus; on the construction of globes, by Signor Césare Pomba; the life and geographical works of Cassini de Thury, by M. Ludovic Drapeyron; an ethnographical map of Europe, by Herr A. von Haardt.

Prof. de Lapparent, Dr. John Murray, and Prof. Penck presided over Section C, where Prof. Palacky read a paper on the geographical element in evolution; Dr. E. Naumann, one on the fundamental lines of Anatolia and Central Asia; Dr. S. Passarge, a third on laterite and red earth in Africa and India; and Mr. Henry G. Bryant, a fourth on the most northern Eskimos. The last paper described observations made in North and South Greenland during the Peary Relief Expeditions.

On Friday (August 2) the President communicated a paper to the general meeting, by Baron A. E. Nordenskiold, on ancient charts and sailing directions. Prof. Hermann Wagner read a paper on the origin of the mediæval Italian nautical charts, which gave some interesting results as to the length of the mediæval nautical mile. Mr. Yule Oldham dealt with the place of mediæval manuscript maps in the study of the history of geographical discovery, and, in the course of remarks on this paper, Mr. Batalha-Reis announced the discovery of an authentic fifteenth century portrait of Prince Henry the Navigator, at Lisbon. The Congress received a number of presentations, and discussed various proposals and resolutions.

Section B—Presidents, Señor Don Torres Campos and M. le Prof. Levasseur—dealt with spæliology (or the science of caverns) and mountain structure. A paper on the method of investigating caverns, by M. E. A. Martel, was read; M. F. Schrader described new instruments and methods used in surveying the Pyrenees; and Prof. Rein gave an account of observations in the Spanish Sierra Nevada.

Dr. F. Naumann occupied the chair in Section C, in which Prof. Penck read an important paper on the morphology and terminology of land forms, and communications were received from Mr. Batalha-Reis on the definition of geography, and Prof. Gerland on earthquake observations.

On Saturday only a general meeting was held. General Annenkoff read a paper on the importance of geography in connection with the present agricultural and economical crisis, and the rest of the time was occupied with resolutions and reports. The President dissolved the Congress in a short concluding address, and bid the foreign visitors a hearty farewell.

After such well-filled days the Congress wisely devoted most of its evenings to recreation. Only two exceptions were made. On Monday night Prof. Libbey showed by the lantern a large number of photographs made in the north of Greenland; and on Thursday Dr. H. R. Mill gave a demonstration in the form of a lecture on the English lakes.

THE BRITISH MEDICAL ASSOCIATION.

THE sixty third annual meeting of the British Medical Association, held in London last week, was the largest in the history of the Association, and one of the greatest assemblies of medical men ever known. Twenty-two years ago the Association held its annual meeting in London, but whereas at that time the membership was only 1500, the number now exceeds 16,000. A large number of foreign medical men were present at the meeting, among them being Prof. Stokvis, Dr. W. W. Keen, Dr. Apostoli, Prof. Mosso, Dr. Fraenckel, Dr. Farkas, Prof. Pozzi, Dr. Ottolinghi, Prof. Lazarewitch, Prof. von Ranke, Prof. Baginsky, Dr. Hermann Biggs, Dr. Ball, Dr. Koster, Prof. Gayet, Dr. Meyer, Prof. Panas, Prof. Fuchs, Prof. Bowditch, Dr. L. A. Nékám, Prof. Baumler, Prof. Martin, Dr Cushing, Prof. Cordes, Prof. Hamburgher, Prof. Marinesco, and Prof. Geikie. Sir T. Russell Reynolds therefore presided over an assembly international in its main aims, and representing an Association as remarkable in its growth as it is high in its standing. It is only possible here to give a few extracts from some of the addresses and refer briefly to a part of the general work of the sections. For these reports we are indebted to the *British Medical Journal*, the organ of the Association. Sir T. Russell Reynolds took for the object of his address "the most striking fact of modern physiological, pathological, and therapeutical research, viz. the power of living things for both good and evil in the conservation of health and in the prevention or cure of disease." In the course of his remarks he said:—"The most important fact with regard to recent microbiological research is the gradually-increasing appreciation of the fact that these lower forms of life exert, not necessarily mischievous, but, indeed, benignant influences on the human body, and that although the mode of their operation is not fully explained they take part in healthy processes, assisting normal functions, nay, indeed, it would seem sometimes producing them and warding off the malign effects of other influences to which we are habitually exposed. These bodies, to which we are indebted for this aid, operate partly by their chemic action and partly by what we must call a vital process, and by their cultivation outside the human body and their modification by passing through other organisms, can be made to exert a malign or a beneficial agency on man. It seems even in the range of possibility that at some time not very distant some other than 'the ancient mariner' may apply to them the far-reaching words of Coleridge, and exclaim

> O happy living things! no tongue
> Their beauty might declare;
>
> * * * *
>
> Sure my kind saint took pity on me
> And I blessed them unaware.

"The third great revelation of the last twenty years is the wonderful protective and curative power of these living products. This, in a very wide sense, is not new. Of all the most powerful agents of destruction, the most violent have been derived from 'living' things; they are to be found in the animal and vegetable worlds, not in the mineral. In their most terrible malignity—such as in snake-bite, glanders, or hydrophobia—these need no human skill for their development: they are prepared in the laboratory of nature, and, alas! are only too ready to our hand. Next to these come the poisons of stinging things, and, after them, the more slowly operating and less deadly animal infections; some with indeed beneficial influence, as 'vaccinia'; others with local effects on the skin, but not often great disturbance of the general health.

"The vegetable kingdom can produce potent poisons, such as belladonna berries, aconite root and leaves, poppy juice, and the ignatian bean; but in order to render these more deadly the hand of man has to come in and prepare nicotine, strychnine, morphine, and the like; just as it may produce, from the mineral or quasi-mineral world, such potent agents as hydrocyanic acid, concentrated acids, and other dealers of destruction.

"The interest in these facts lies in the modern mode for their utilisation. The great potency of living products has led to very fanciful notions in therapeutics; and there have been those who, to cure diseases of organs, have given portions of the same but healthy organs of animals or of man or other animals. Again, the idea has been pronounced that even excreta were useful drugs, and that the diseased organs of man might effect a cure of those supposed to be afflicted in like manner.

"Curious as some of these details are, they are of real interest to us only as they lead up, through inoculation for small-pox, to our own Edward Jenner's discovery of vaccination, and then, through the researches of Pasteur, Lister, and Brown-Séquard, to our present state and plane of knowledge. It would seem now that there is scarcely any limit to what may be expected in the cure or prevention of disease; and the most striking of all phenomena is, to my mind, the probability of rendering an animal immune by the introduction into its organism of a healthy constituent of the body of another. This, if fully confirmed, will be the greatest veritable triumph of therapeutic and preventive medicine, instituted and guided by extended inquiry into comparative anatomy, physiology, and pathology. As in the human race or species there exist, as is well known, what may be termed 'idiosyncrasies'—by which is simply meant that as a matter of fact some people, and some people's families, escape epidemic diseases, whereas they are especially prone to take others to

which they may be exposed—so in the great economy of Nature certain groups of animals have been shown to exhibit no capacity for 'taking,' or for even being 'inoculated' with the poisons to which others are exposed, and from which they suffer, and that severely. It would seem, therefore, that use may be made of these animals, more or less naturally immune from certain maladies, and that their immunity may be partially conferred on man.

"Quite recently a communication of the greatest importance has been made on the rendering of animals immune against the venom of the cobra and other snakes, and on the antidotal properties of blood serum of immunised animals. This subject has occupied attention during the last six years, and we must all look forward with expectancy and hope to the possible and probable diminution of a great national and imperial calamity.

"The outcome of what I have been saying is this: that the scattered fragments of knowledge and 'guesses at truth' of many years have been gathered into a focus during the past twenty-five years; that the vegetable life, extracting from the mineral world the materials it needs for growth and production of powerful agencies for good in the form of food and medicines, and for evil in the form of poisons, has given itself up to the growth of animal life, with its much more complex organs, and for cure of ills once thought beyond the reach of human aid; but that, thanks to man's scientific ardour and industry, it has again shown itself to be our servant, our helper, and our protector.

"These are not dreams of the study, they are facts of the laboratory and of daily life; and in using that word 'life' again, I must endeavour to emphasise still more forcibly upon you my urgent belief that it is to living agencies and their employment that we must look for help in the care of infancy, the conduct of education—moral, mental, and physical—the training up of character as well as of limbs; that it is the guidance of living functions, in the choice of living occupations, be they either of hard work or of amusement. It is to these we must appeal if we would see the *mens sana in corpore sano*; and then it will be to these that we may confidently look for help when the inroads of age or of disease are at hand, often to cure us of our trouble; or, if not, to give us rest and peace.

"It would be absurd in me, now and here, to attempt to say in what this potency of life exists. It is enough for us to recognise its existence, rejoice in its marvellous energy, and anticipate still more from our investigations of its modes of action, but I cannot help feeling that, however far we go in our research into the arcana of nature, one of our ablest neurologists, who has gone very far, is right when he says: 'Search while you may with eyes, however aided and however earnest, that which we call "life," eludes our search and resists our efforts. We must be content with what knowledge we can gain, secure or insecure, and while using it as best we may, should realise in all humility how much there is we cannot know, and yet we cannot doubt.'"

An address in medicine was delivered by Sir William Broadbent, who traced the growth of the art and science of medicine. He pointed out that of the infancy of medicine properly speaking nothing is known.

Individual acts of healing are related in the Old Testament, and the treatment of wounds is described by Homer; the Chinese from remote antiquity had a system of medicine, and medicine has a place in the *Vedas*; but in the works of Hippocrates, who was born about 460 B.C., the earliest medical literature which has been handed down, the theory and practice of the art of healing is shown in a considerably advanced stage of development. The development of medicine from that time was sketched by Sir W. Broadbent in an admirable address, and the great advances made during the present century in the many departments of his subject were touched upon. In one of the sections, the excellence and defects of modern therapeutics were passed in review as follows:—

"We have still to ask, What is the bearing of all these advances of knowledge on therapeutics, which, after all, is the object of our lives?

"Until the last few years it has not been easy to answer this question by instances of any very extensive applications of physiology to the treatment of disease, and morbid anatomy was at one time a stumbling-block in the way of therapeutic effort. The pathologist, pointing to an excavated lung or cirrhosed liver, would ask the physician what he could expect to do with drugs against such conditions. But that stage has passed away, and I will not mock your intelligence by other illustrations beyond those just given of therapeutic applications of physiological and pathological knowledge, or by arguing that all knowledge of normal processes aids in the comprehension of morbid processes, and that we are in a better position to combat disease when we thoroughly understand its causation and initiation, and follow mentally its development, course, and tendencies.

"Given the faculty of observation, the insight which penetrates the meaning of the phenomena, the analytical and synthetical powers by which a diagnosis is constructed, the ready adaptation of means to a well-defined end, and the firmness of character required to deal with the frailties of human nature, and the best physiologist will make the best pathologist and the best pathologist the best physician.

"As regards the remedies at our command, they are only too numerous. Recourse to a great variety of drugs is fatal to exact knowledge of their effects and to precision in their use, but new ones are added every day for the benefit chiefly of those who do not know how to employ the old ones. There have, however, been recent acquisitions of extreme value, heavily discounted, unfortunately, in the case of some by the mischief done through their indiscriminate use: the antiseptic group, the chloral sulphonal group, the salicylates and salicine, the phenacetins and antipyrin class, coca and cocaine. What makes some of these, moreover, far more important and interesting is the fact that their physiological action has been inferred from their chemical constitution.

"A fact which brings practical therapeutics into near relation with physiology and pathology is that the active principles of all drugs are isolated, their chemical composition is ascertained, and their physiological action investigated. Pharmacology, in effect, has become a branch of experimental physiology, and the immediate effect of remedies is known with a completeness and accuracy heretofore undreamt of. All this is working towards a more intelligent employment of drugs, and leads towards the goal of all the efforts to bring therapeutics within the circle of the sciences. This goal is that we should know not only the effects of remedies, but how these effects are produced. This is in the last resort a question of chemistry. As I have said before, all vital actions are attended with molecular or chemical changes; are, from one point of view, chemical action, and come under the laws of the correlation of force and conservation of energy; so, therefore, are the physiological and therapeutical action of drugs, and obviously the key to the latter is to be found in the chemistry of vital processes. Therapeutics, to become scientific, is only waiting for answers to the questions which she puts to chemistry. Why are sodium salts so much more abundant than potassium salts in the blood, and why are the former almost confined to the liquor sanguinis, and the latter to the corpuscles? We must assume that albuminoid proteids have an affinity for sodium, and the globulins for potassium. With the answer to this is bound up the secret of the necessity of sodium, potassium, and calcium salts to anabolic and catabolic operations, in which they take no traceable part, and of the presence of iron in the blood corpuscles.

"Why, again, in the case of substances apparently so similar as potassium and sodium salts will the former, if injected into a vein, even in small quantity, paralyse the heart and destroy life, while we see pints of normal saline solution thrown into the circulation with none but good results? How does prussic acid—the simplest in composition and constitution of all organic substances—prove fatal with such fearful promptitude by its presence in infinitesimal proportion in the blood? How again does morphine suspend the activity of the nerve centres? Chemists must admit that the poisonous effects of prussic acid and morphine can only be due to some molecular change in these substances; they know that if the deadly cyanogen is so tied up that its component atoms cannot fly apart it is innocuous, and that a very slight change in the chemical constitution of the morphine molecule entirely alters its effect; it is an almost irresistible inference from the doctrine of conservation of energy that the change in the molecule, say of the morphine, must be equal and opposite to the molecular change in the nerve cells which it arrests. It seems to me, therefore, that we have in the chemical constitution of the morphine molecule a clue to the character of the chemical change by which nerve action takes place and to the quantivalence of nerve energy.

"What then is our position to-day in respect of the three points which we have been following—the recognition of disease, the

knowledge of remedies, and the ideas which govern the employment of remedies in the treatment of disease?

"The basis of therapeutics is diagnosis, the grasp of the actual condition underlying the symptoms or phenomena, and the greater our command of powerful remedies and the more precise our knowledge of their effects and of the mode in which these effects are produced, the more important does accuracy in diagnosis become.

"A diagnosis, to be real, implies not only the recognition of the disease which may be present and an accurate appreciation of the morbid changes which may have taken place in various organs. It embraces a knowledge of the nature and intensity of the pathological processes which have been and are in operation, and of the causes which set them going, and also of the results to which they tend. A further element, moreover, enters into the consideration; an estimate, by the aspect of the patient, by the pulse and temperature, and by other subjective and objective indications, of the impression made on the system, and of the resistance which it is capable of to the lethal tendencies of the disease.

"Year by year we see improvement in this respect; not only that hospital physicians and teachers endeavour to carry diagnosis to a greater pitch of accuracy and a higher point of refinement than ever before, but that the entire body of medical men are trained by improved education and systematic clinical teaching to appreciate and to practise careful diagnosis in their daily work.

"Diagnosis, we may say, has reached an extraordinary degree of advancement. There are, no doubt, still new fields to conquer, but in the recognition of diseases, local and general, there is not much which seriously concerns the human race which remains to be done. The same degree of knowledge, however, does not extend to morbid processes. Our comprehension of the significance and essential character of inflammation is by no means complete and satisfactory. The part which fever plays and the place which it holds among the phenomena of disease is far from being fully understood. It cannot have been intended by nature for the destruction of the subject, and we can see distinctly that in some cases it forms part of the defensive operations; possibly, indeed, its general tendency is defensive, by promoting the production of phagocytes, or possibly a certain elevation of the temperature may be fatal to maleficent organisms which have taken possession of the blood or tissues. We are not certain, indeed, whether in pyrexia the heat-producing oxidation in the structures receives its stimulus from, or takes place at the bidding of, the nervous centres, or, on the other hand, is due to enfeeblement of the restraint which they normally exercise over it, or whether it defies control by the thermo-taxic nervous centres."

An address in surgery was delivered by Mr. Jonathan Hutchinson, who gave a brief retrospect of the surgery of the past, interspersed with a few comments as to what may be hoped for the future.

Prof. Schafer delivered an address in Physiology, taking for his subject "Internal Secretions." After describing various glands and secretions and their method of interaction, he said: The general results to which we are led point very strongly in favour of the notion that internal secretions are yielded both by the ductless glands and by what are usually known as the true secreting glands, and it is obvious that such internal secretions may be of no less importance than the better-recognised functions of the external secreting glands. That a failure of one or other of these internal secretions has to be definitely reckoned with by the physician there can be no doubt whatever, while at the same time the therapeutist will be able to avail himself of the active principles which the internally secreting organs afford, and in certain cases to use their extracts in place of the hitherto more [illegible] employed vegetable medicaments.

The work of the different sections covered a wide range, and [illegible] related purely to medical practice. It will be [illegible], therefore, for us to indicate by the following summary [illegible] of a few of the more important papers [illegible] reported in the *British Medical Journal*.

Section of Medicine.

The President, Dr. Pavy, opened the proceedings in this Section with an address in which he described the progress in [illegible] discovery of the casual relationship existing between [illegible] and certain diseases, enlarging upon the [illegible] effect that this had had upon the question of treatment, and upon the control that could be exercised upon the spread of infectious diseases. He briefly touched upon the serum treatment of diphtheria. Dr. Sidney Martin then introduced the discussion on diphtheria and its treatment by the antitoxin. Dr. Martin commenced by stating that there had always been two schools of therapeutists with regard to the treatment of diphtheria, the one trying to discover some local application which would loosen or remove membrane in the throat, and the other to provide a remedy that would act upon the general symptoms of the disease. The want of success in the past made it essential, in his opinion, to examine most carefully into any new method of treatment suggested, and to submit it to a most rigid scientific inquiry before accepting it. The antitoxin treatment, he stated, had been studied with the greatest care, and its recommendation was based upon the results of a consideration of the pathology of the disease.

Prof. von Ranke (Munich) stated that whilst in 1892 he had in his hospital a mortality of 56·2 per cent., in 1893 of 46 per cent., and in 1894 up to September 24, when he had commenced the serum treatment, one of 57 per cent., since that time his death-rate had been reduced to 17·7 per cent. He further considered that not only was the reduced death-rate due to the injection of antitoxin, but that the course of the disease was favourably influenced in the most striking manner. Prof. Baginsky, of the Empress Frederick Hospital, Berlin, though not speaking with the high enthusiasm of Dr. Ranke, yet gave equally startling figures, stating that whilst the mortality in the four years previous to 1895 had been on the average 41 per cent. under the old system of treatment, during the last year, under the serum treatment, it had been reduced to 15·6 per cent. Dr. Sims Woodhead spoke briefly upon the importance of using large doses of serum, and concluded by quoting some Paris statistics which were highly favourable. Dr. Hermann Biggs (New York) then gave a most interesting account of the immunising effect of the serum, quoting figures to show that in almost all cases the immunising power of the serum extends to a period of thirty days. He further stated that out of 800 healthy children who had received injections, he had not seen a single case in which any harm had resulted from the treatment.

Section of Surgery.

Sir William MacCormac, President of the Section of Surgery, took for the subject of his address "Some Points of Interest in Connection with the Surgery of War." He came to the following conclusion:—

"It would appear probable that in a future war many of the wounds produced by the new projectile will be surgically less severe, and prove amenable to effective surgical treatment. Probably also the number of severe injuries will be very great when we consider the enormous range of the new weapon and the penetrating power of the projectile, which enables it to traverse the bodies of two or three individuals in line, including bones, and to inflict serious or fatal wounds at a distance of 3000 or 4000 yards. It is impossible to say what the proportion between these two is likely to be. At near ranges the explosive effects will be much the same as before; but at long range the narrow bullet track, the small external wounds, which often approach the subcutaneous in character, and the moderate degree of comminution and fissuring of the bone will be surgically advantageous. These will form the bulk of the gunshot injuries of the future, for it would seem impossible with magazine quick-firing rifles to maintain a contest at close quarters without speedy mutual annihilation.

"We may take it for granted that the number of wounded, in proportion to the numbers engaged and actually under fire, will be greater than before. The supply of ammunition will be larger, the facility for its discharge greater, and smokeless powder will increase accuracy of aim.

"I think we are justified in believing, although there is high authority for a contrary opinion, that the next great war will be more destructive to human life, 'bloodier,' in fact, than any of its predecessors; and that the number of injuries, and in many cases the severity of the injury, will be largely increased. But very many cases will remain less severe in character, more capable of successful treatment, and less likely to entail future disablement, while improved sanitation and antiseptic methods will enormously increase the proportion of recoveries.

"It is the unceasing effort of modern surgery to provide antiseptic protection in an effective form in time of war; and I may be permitted to recall that the medical organisation during our

last war in Egypt was so complete in this respect that not a single case of infective wound disease occurred during the whole campaign.

"As a temporary dressing, some form of antiseptic occlusion will prove most generally applicable. The small wounds of entrance and exit render this plan comparatively easy of application, and the chances of septic infection will be diminished by the less frequent necessity for probing or searching for a lodged projectile, and, indeed, the ascertained presence of the bullet is no sufficient indication *per se* to attempt its removal. The eye, rather than the hand, is the best thing to employ at a first dressing station, as Fischer has well said.

"If only asepticity can be ensured—and this is the great difficulty—we may expect a large measure of success to follow the treatment of wounds of the soft parts, many forms of fracture—notably also wounds of the joints, and very especially wounds of the lung."

Section of Public Medicine.

The proceedings in this Section were opened by Mr. Ernest Hart, who delivered an address on "Public Health Legislation and the Needs of India." Mr. Hart strongly criticised the whole system of the sanitary service and the medical service of India, and held that it needs to be overhauled and reconstituted.

"What is urgently needed," he said, "is a Royal Commission or strong Departmental Committee to inquire into the whole matter, and to institute a radical change. For at present India is decimated by preventable diseases; the health of our troops is ruined by the same causes. With us lies the reproach of nursing and fostering cholera in what is called its endemic home—a purely ignorant and silly phrase. Until some great change is made in the whole system of the present administration, the great sanitary needs of India will never be met."

Section of Pharmacology and Therapeutics.

In this Section, under the presidency of Sir William Roberts, there was a discussion on Sero-Therapeutics, embracing the application of serum treatment, not only to the acute infective disorders, but also to the cure of bites from venomous serpents. In his introductory remarks the President drew attention to a hitherto much neglected alkaloid of opium, generally known as "narcotine," but more properly termed "anarcotine," from the complete absence of narcotic properties. A large amount of evidence was available which seemed to show that this alkaloid has very valuable antiperiodic powers, which, should further investigation corroborate, will render it a valuable remedy in certain cases of malaria in which quinine entirely fails. The discussion on Sero-therapeutics was opened by Dr. Klein in a paper on the nature of Antitoxin. He drew attention particularly to the differences in action between a protective serum obtained from animals immunised by injections of filtered diphtheria toxin, and by those treated with living cultures of the diphtheria bacillus. He had found that while the first had an extremely high neutralising power on the chemical poison separated from the bacilli, it had not nearly so marked an immunising power. On the other hand, an antitoxin prepared with the aid of living cultures, while it was less active than the other in neutralising toxins, was far more efficacious as an immunising agent. He also gave brief hints on the advantage of using a dried serum in place of the usual liquid form, and stated that the use of the former was far less likely to be followed by the appearance of rashes and other complications.

Other Sections.

Dr. Mickle, President of the Section of Psychology, delivered an address on the abnormalities occurring in the form and arrangement of brain convolutions. The Section of Physiology was opened by Dr. Ferrier with an address on the relations of physiology and medicine. In the Section of Anatomy and Histology, Mr. Henry Morris, in his presidential address, gave a brief history of the rise of artistic illustration in its relation to anatomical teaching.

The presidential address in the Section of Pathology and Bacteriology was delivered by Dr. Samuel Wilks, F.R.S. In the course of his remarks he drew attention to the fact that every pathological process is accompanied by a corresponding reparative process, and lamented that sufficient regard had not been paid to the distinction between these constructive and destructive processes. To study these for the sake of discovering the several influences exerted in the production of each is of great practical import; and a consideration of them also shows that pathology is governed by the same laws as those which exist in every other department of nature, and therefore must take its place on an equivalent footing with the other sciences.

Mr. H. Power, the President of the Section of Ophthalmology, remarked on the work that had been done by the founders of ophthalmology in the past, and the gradual formation of a scientific branch of medicine, of which the methods of diagnosis and treatment were fortunate in being founded on pure science. Owing to its intimate relations with the other branches of medicine and surgery there was no danger of its separating from the parent stem and becoming barren; at the same time he advocated a sounder education in the sciences on which ophthalmology was established, such as mathematics and physics, being required of all candidates for ophthalmic posts in hospitals.

Bacteriological Exhibits.

A collection of exhibits brought together to illustrate points of general pathological interest was on view during the meeting. Bacteriological exhibits made up one of the departments of the temporary museum thus formed. Dr. Cautley exhibited cultures and coverglass preparations of an organism found in seven out of eight cases of the affection usually termed influenza cold. It was of special interest and importance as showing, first, that the disease in question is microbial in origin, thus explaining the frequency with which such colds affect all the members of a household; secondly, that it possesses a certain relationship to epidemic influenza. The biological characteristics indicated that the organism is allied to the organism of epidemic influenza. Morphologically the organism presented a further point of interest, many club-shaped forms, similar to those of the diphtheria bacillus, appearing in the specimens. Some excellent photographs of the specimens accompanied the exhibit, and were taken by Mr. E. C. Bousfield.

The cultivations from the laboratories of the Conjoint Board of the Royal College of Physicians, London, and of the Royal College of Surgeons, England, were permanently fixed by formic aldehyde. This substance arrests the growth almost at once, and after the lapse of two or three days kills the bacilli. Various organisms in culture illustrated this method, and showed its applicability to museum and other specimens.

Drs. MacFadyen and Hewlett exhibited from the Bacteriological Department of the British Institute of Preventive Medicine a complete series of cultures of the most important micro-organisms, and Mr. Joseph Lunt exhibited living cultures of various water organisms isolated from drinking water, sewage, air, &c., together with some interesting instances of enzymes filtered from both cultures of various organisms, possessing liquefying and other properties similar to those possessed by the parent organisms.

Dr. Klein showed a large number of photographic lantern slides representing nearly all known pathogenic bacteria, and, amongst others, duplicates of Mr. Bousfield's work for the influenza and cholera reports, the latter especially showing vibrios with their flagella with wonderful clearness.

SCIENCE IN THE MAGAZINES.

FOUR short papers on Huxley appear in the *Fortnightly Review*. The Hon. G. C. Brodrick, Warden of Merton College, Oxford, records some personal reminiscences of the man whose loss is so keenly felt. It appears that about thirty-seven years ago, when a Linacre Professorship of Physiology, coupled with Human and Comparative Anatomy, was founded, Huxley meditated becoming a candidate for the chair. Before the election took place, however, he made up his mind not to seek the office, which was awarded to the late Prof. Rolleston. The reason he assigned was that his opinions were too little in harmony with those prevalent at Oxford. This opinion he again gave, but with diminished emphasis, when he was asked, twenty years later, to accept the chair, upon the death of Prof. Rolleston. His work for the advancement of anthropology forms the subject of a note by Prof. E. B. Tylor. "Close upon the end of his life," says Prof. Tylor, "Huxley did his best to promote the scheme to make anthropology at Oxford an examination subject for an Honours degree in Natural Science. Writing to me, he said, "If I know anything about the matter, anthro-

pology is good as knowledge, and good as discipline.' But Convocation thought he did not, 'know anything about the matter,' and threw out the proposed statute." Huxley's career as biologist is sketched by "A Student of Science." The following is worth quoting from that contribution. "It was characteristic of the Professor's general mental attitude that mere novelty never affrighted him. When Ramsay propounded his theory of the excavation of lake basins by glacial action, Huxley supported it, even against the opposition of Lyell and Falconer. Suppose St. Paul's Cathedral removed from its present site to any part of the North Sea, the English Channel, or the Irish Sea, and the whole dome would be clear out of water. Place it, on the other hand, on the flow of Loch Lomond, and the largest ship in the British Navy might float safely over the golden ball, for the Loch has a maximum depth of 630 feet. Sir Andrew Ramsay's theory explains a striking fact like this, and affords undoubtedly a rational explanation of many similar phenomena." The fourth of the papers treats of Huxley as philosopher, and is by Mr. W. L. Courtney, the editor of the *Fortnightly*. Under the title "The Spectroscope in Recent Chemistry," Mr. R. A. Gregory contributes to the same review a brief history of the discovery of argon and helium, and discusses the many interesting points raised by the advent of those two new terrestrial elements, especially with reference to their spectra. It is worthy of contemplation that, so far as instrumental possibilities go, both argon and helium could have been discovered spectroscopically many years ago, and Lord Rayleigh would have been saved his years of tantalising experimentation. And yet there are some who think that the spectroscope will not help much more in the extension of natural knowledge!

The evolution of the orator and poet, actor and dramatist, is traced by Mr. Herbert Spencer in his fourth paper on "Professional Institutions," which appears in the *Contemporary*. First in his story of development comes the orator, who proclaimed the great deeds of a victorious chief during the triumphal reception; then was evolved, through natural selection, the poet, who, with picturesque phrases and figures of speech, gave rhythm to the laudatory speeches. Gradually the orator or poet joined with his speeches mimetic representations of the achievements of the living or the apotheosised ruler, or else they were simultaneously given by some other celebrant. So the actor was produced, and as more complex incidents came to be illustrated by speech and action, it was necessary for one to arrange the parts to be played, and thus the dramatist was developed. In support of this very natural sequence, Mr. Spencer adduces a variety of evidence supplied by uncivilised races and by early civilised races. Another paper in the *Contemporary* consists of extracts from Mr. E. A. Fitzgerald's journal of his ascents of virgin peaks in the New Zealand Alps. Five new peaks were ascended, namely, Sealy, Silberhorn, Tasman, Haidinger, and Sefton, the Matterhorn of the range. He also discovered a pass which has received his name, and across which the range has now been traversed to the west coast. Several attempts had previously been made to find such a route, but unsuccessfully. Mr. Fitzgerald's paper will therefore not only be read with interest by lovers of Alpine adventure, but will also be valued by the geographer.

The story of Antarctic exploration is told in *Macmillan's Magazine*, and the movement for further researches in those higher southern latitudes is given support. It will be remembered that the efforts made by the Royal Geographical Society, in connection with a committee of the Royal Society, to induce the Government to fit out an expedition for exploring in the Antarctic Ocean, were not successful. Notwithstanding this, the writer of the article expresses the general opinion when he says: "When it is undertaken at all it is desirable that the next Antarctic expedition should be a national one. Private enterprise, which has been splendidly active of late in the way of Arctic discovery, would scarcely be equal to all the demands of extensive and thorough Antarctic exploration."

A passing notice must suffice for the remaining articles of more or less scientific interest in the magazines and reviews received. A brief sketch of the characteristics of Sonya Kovalevsky is given in the *Century*, and one of the concluding sentences read: "Notwithstanding her solid contributions to applied mathematics, she originated nothing: she merely developed the ideas of her teachers." A number of elementary facts with reference to the transporting power of water and the deposit of sediment, are stated by Mr. W. H. Wheeler in *Longman's Magazine*. The *National* contains an article, by Mr. J. L. Macdonald, on fruit-farming in California, which is worth the attention of agriculturists. In the *Quarterly Review*, roses and rose cultivation are surveyed, though more from an historical than a scientific point of view. An *Edinburgh Reviewer* discusses organic variation and animal coloration, basing his remarks upon Mr. Bateson's "Materials for the Study of Variation" and Mr. F. E. Beddard's "Animal Coloration." In *Good Words* we find an illustrated article by Dr. Bowdler Sharpe, on curious nests of birds, and a paper on the Earl of Rosse and his great telescope, by Sir Robert Ball. *Chambers's Journal* contains, among other instructive articles, one on the U.S. North Atlantic Pilot Chart, and another on "Taka Joli," a new substitute for yeast. Finally we have to acknowledge the receipt of *Scribner's Magazine*, the *Sunday Magazine*, and the *Humanitarian*.

PHOTOMETRIC STANDARDS.

THE following Report of the Committee appointed by the Board of Trade, in December 1891, "to inquire into and report to them upon the subject of the standards to be used for testing the illuminating power of coal gas," has just been published as a Parliamentary paper.

"(1) It was intimated to us, by a letter from the Secretary to the Board, that the method at present in use for measuring the illuminative value of coal gas has been objected to, alike by the Metropolitan Gas Referees and the London County Council, as being of an unsatisfactory nature: that the London Gas Companies are alive to the defects in the present system; and that legislation is admittedly necessary for the purpose of substituting a more trustworthy standard for that now in existence; but that, in view of the difference in opinion as to what the substituted standard should be, the President of the Board deemed it advisable that, before his support was given to any legislation, the whole question should be considered by a Committee that would command the confidence of the various interests affected.

"(2) The method at present in use for measuring the illuminative value of coal gas consists in comparing the light of the gas, when burning from a particular burner at a specified rate, with the light of a sperm candle burning also at a specified rate, which last is taken as a standard. We have satisfied ourselves, from considerations set forth in the Appendix to this Report, that the flame of a sperm candle does not furnish a satisfactory standard, by reason of the amount of light which it affords varying over a wide range, under conditions as to the manufacture of the candle, as to its mode of use, and as to adventitious circumstances attending its use, which, as a whole, it is not possible to regulate and define.

"(3) Though recognising, however, that the sperm candle flame does not furnish a satisfactory standard, we nevertheless consider it advisable that, in official documents and reports, the quantity of light yielded by coal gas burned under specified conditions should continue to be expressed as heretofore, in terms of candle-light, the actual comparison, however, being made between the gas-light and some well-defined and constant light ascertained to be equal in quantity to, or a definite multiple of, the average light given by the standard sperm candle.

"(4) We have further come to the conclusion that, in the present state of experience and knowledge, the source of the light to be used as a standard by gas-testers generally must be produced by the process of combustion, and be in the nature of a flame.

"(5) We find that the one-candle-light flame proposed by Mr. A. Vernon Harcourt as giving a standard light, and commonly known as the 'Harcourt pentane air-gas flame,' when used under the conditions defined, does constitute a very exact standard, capable of being reproduced at any time without variation of illuminative value.

"(6) We have satisfied ourselves that the light given by Mr. Harcourt's above-mentioned pentane air-gas flame as defined, in respect to the conditions of its production, in the Appendix, is a true representative of the average light furnished by the sperm candle flame constituting the present standard. Since 1879, when the pentane air-gas flame was first introduced, many series of experiments have been made by different observers, in which the light of the proposed standard has been compared with the light of the standard sperm candle

flame, with the result that in those series of experiments in which the height of the pentane air-gas flame was adjusted strictly according to the directions given in the Appendix, the light afforded by this flame was found to agree exactly with the mean result afforded by the standard candle flame. In other series of experiments, indeed, in which a slight variation was made in the mode of adjusting the height of the pentane air-gas flame, some discrepancies in the direct results furnished by the comparison of its light with that of the standard candle flame were observed; but in these several series of experiments also, when the necessary correction, called for by the difference in the mode of adjustment resorted to, was made, the light of the pentane air-gas flame was found to accord closely with the mean result afforded by the standard candle flame.

"(7) Inasmuch, however, as there is a practical advantage in comparing directly the light of such a coal-gas flame as is usually tested (being, that is, of about a sixteen-candle-light value), with a light approximating somewhat in value thereto, we have further submitted to careful examination the flame of the ten-candle-light pentane argand proposed as a standard by Mr. W. J. Dibdin in 1886. This flame is produced by burning a mixture of air and pentane vapour from a suitable argand burner, provided with an opaque screen by which the light from the upper portion of the flame is cut off. The screen being set at a definite height, it was found by Mr. Dibdin that, owing to a compensating action affecting the lower or exposed portion of the flame, the luminosity of this portion of the flame remains constant even under considerable variations, whether in the total height of the flame or in the proportion of pentane vapour to air in the mixture burnt. With a view to simplify the construction of the argand burner furnishing a cut-off flame of this constant luminosity, we have tried various changes in the form of the cone and in the division of the air supply to the flame, but in every case have found the original burner, as supplied by Mr. Sugg for the purpose, to give more satisfactory results than the modified forms.

"(8) The amount of light emitted by the portion of the Dibdin argand pentane-air flame that is used in photometry, being dependent on the distance above the steatite ring of a screen by which the upper part of the flame is cut off, we have come to the conclusion that when the bottom of the screen is fixed at a height of 2·15 inches (54·6 mm.) above the top of the steatite ring, the amount of light emitted by the lower portion of the flame is substantially equal to ten times the average light of a standard sperm candle flame, or to ten times the light of Mr. Harcourt's one-candle-light pentane air-gas flame.

"(9) We have further satisfied ourselves that any number of Dibdin argand burners may be produced, having the form and dimensions set forth in the Appendix; and that these several burners, when used in the manner there defined, may be depended on to furnish a flame giving, when duly screened on the top, ten times the average amount of light given by a standard sperm candle.

"(10) We therefore recommend that the pentane-air flame furnished by a Dibdin argand burner, having the form and dimensions set forth in the Appendix, and used in the manner there defined, be accepted as giving the light of ten standard candles, and that this flame be authorised and prescribed for official use in testing the illuminating power of the gas supplied by the London Gas Companies.

"(11) We further recommend that sealed specimens of the burner, the carburetter, and the pentane for use therewith, duly certified by the Gas Referees, be deposited with the Board of Trade, and also in such places and in the care of such persons as the Board may direct, to be available for the purpose of comparison, in the event of any question arising as to whether the pentane-air flame of some particular burner does or does not afford the same amount of light as that now proposed for adoption as a standard.

"(12) With a view to making some provision for future possible improvements and requirements, we further recommend that the Gas Referees be authorised, should they at any time see fit, to approve and certify for use in gas-testing any other flame based upon the 10-candle standard defined above, which they may consider suitable for the purpose, whether produced in a like or unlike way, and whether having the same or a different multiple value; such other flame, however, not to be used for gas-testing unless approved by the Board of Trade, and unless the Gas Companies give their consent to its adoption as a standard.

"(13) We further recommend that the illuminating power of coal gas shall continue to be recorded as heretofore in terms of the light given by a specified number of cubic feet (to wit, 5 cubic feet) burnt per hour from the standard London argand burner, but that, in testing the illuminating power of the gas, the requirement that the gas shall actually be consumed at this rate be rescinded, so as to allow the Gas Referees to sanction a mode of testing in which the gas shall be burned from the standard London argand burner at whatever rate is found requisite in order that it may give a light equal to that of the prescribed number of candles, and in which the illuminative value of the gas shall be calculated as being inversely as the rate at which such gas had to be burned during the testing so as to give this amount of light."

The Report is signed by Prof. William Odling, F.R.S. (Chairman), Mr. W. J. Dibdin, Dr. E. Frankland, F.R.S., Dr. A. Vernon Harcourt, F.R.S., Mr. George Livesey, Dr. William Pole, Mr. George Rose-Innes, Prof. A. W. Rucker, F.R.S., Dr. W. J. Russell, F.R.S., Mr. G. C. Trewby, and (subject to the omission from (13), line 7, of the words "the Gas Referees to sanction") by Mr. H. E. Jones. Prof. Vivian B. Lewes was the Secretary of the Committee.

SCIENTIFIC EDUCATION IN AMERICA.

UPON the occasion of the laying of the corner-stone of a new building for a Museum for Dartmouth College, Hanover, U.S., Prof. A. S. Bickmore recently delivered an address, in the course of which he dealt with the methods of scientific instruction in America. The College was originally designed to elevate the Indian race in America, hence its location at Hanover, New Hampshire, in 1770. It was named after Lord Dartmouth, who took a deep interest in the aborigines of the New World, and who was the principal benefactor of the school established for their education.

We extract the following from the report of Prof. Bickmore's address in the *New York Times*:—

"The present is pre-eminently an educational age, and the princely gift from one of our alma mater's loyal sons for the purpose of endowing a 'professorship of palæontology, archæology, ethnology, and kindred subjects, and for the erection of a building for preserving and exhibiting specimens illustrating the aforesaid branches,' is in perfect harmony with the judgment of the leading educators of our times, namely, that the greatest benefit it is our privilege to confer upon coming generations is to provide ever-increasing means for their mental improvement.

"As we meet to-day to lay the corner-stone of the noble edifice so generously provided for by the late Dr. Ralph Butterfield, and to celebrate the commencement of a structure which will add so largely to the educational facilities of this college, I invite you to consider with me, as a subject suggested by this occasion, 'The Place in Modern Education of the Natural Sciences and their Museums.'

"In a period which will ever be famous in history for the great donations that are being constantly made by our private citizens for the public good, it is worthy of our careful consideration that the most munificent gifts are almost exclusively for the purpose of promoting education. In the United States where even the existence of 'a Government for the people and by the people' must ever rest upon the intelligence and the integrity of each individual citizen, it is not a matter of desirability, but simply one of necessity, that the promotion of public instruction shall ever be a question of paramount importance.

AMERICAN SYSTEM OF TEACHING.

"Our American system of instruction may be rapidly summarised. First and lowest is the kindergarten, which may be regarded as still in its experimental stage, but which is certainly destined to become one of our most effective methods of mental training. Next come the public schools, supported by taxation, with their primary and grammar grades, and the high schools and private academies. Above these are the colleges, with their ever-increasing series of elective studies; and then the universities, with their special schools of science, medicine, law, and theology; and finally, the great post-graduate institutions, composed of entirely distinct corporations for the creation of great museums of science and art, and the accumulation of exhaustive libraries.

"As nearly as it is possible to ascertain, we have been expending twice as much per individual for public education as England, but as she increases her grants for that purpose, our provision must be enlarged in the same ratio, and especially ought we to introduce the latest and most improved methods for imparting instruction.

"The National Educational Association, at its meeting at Saratoga in 1892, appointed a committee, with President Eliot at its head, to suggest improvements in the studies of our secondary schools, and in their report those educators state their opinion that 'the study of both plants and animals should begin in the lowest grade, or even in the kindergarten, and that such studies, with geography subsequently added, ought to count in an examination for college.' Indeed we find the latter study already in the curriculum of Harvard University. In 1882, just ten years before President Eliot's committee was appointed, we began to seek to render our Museum of Natural History in New York City an aid to the instruction given in our public schools, by placing in each of them a small cabinet of the rocks, corals, shells, insects, and birds of our own country. We also organised for the teachers a series of illustrated lectures, describing the collections on exhibition in our halls, and picturing the regions from which they came. Our first audience consisted of twenty-five teachers and three officers of our Board of Education. Last year, under the auspices of the State Superintendent of Public Instruction, we spoke directly at the museum, and indirectly by the repetition of our lectures elsewhere, to 103,000 of our educators and other citizens, and now, through a provision made by the last Legislature, our visual instruction will be repeated in the public schools of every city in our State, and in all the villages having a population of 5000 and upward, so that during the coming year we shall reach 800,000 pupils, besides large audiences of adults on the public holidays. The measure of success that has attended our labours has been largely due, first, to our belief that it is the duty and the privilege of every educational institution of every grade to try to render a distinct benefit to each class of the citizens, wherever it may be located, and, secondly, to the illustrative method employed based on the maxim that 'the eye is the royal avenue to the mind.'

"To the question, what kind of a collection in natural history should be desired for each of these grades of instruction, we would reply that it should exactly correspond to the curriculum of study adopted by that grade. A college museum should possess a full series of the animals, plants, and minerals of the State in which it is situated, with typical specimens of the orders of these natural kingdoms from other States and other Continents; and also a library that will enable its teachers to keep up with the general progress of their departments. Even this simple plan may be made to absorb more money than most of our colleges are likely to acquire for such purposes during many generations, on account of the unfortunate tendency in these times for many a friend of education to found a new institution which may bear his name.

"In this presence I hardly need to add that every student should be encouraged to improve his leisure hours in taking long walks through all the region surrounding his place of study, in order to make his own observations and his own deductions upon the physical geography and geology of the places visited. His vacations may in this way become quite as important as the same length of term time. If during these travels he will gather minerals, fossils, or make a small cabinet of botanical specimens or insects, he will not only gain important information, but will have discovered the true mode of gaining by healthy exercise [illegible] that relaxation which is a necessary condition to the [illegible] the recitation room; and whatever may be his [illegible] occupation, thankful indeed will he be that he [illegible] early to learn how to forget the overwhelming [illegible] life, and that therefore he is able once more to [illegible] nature as restfully as he did in his college days.

"A [illegible] which has courses of post graduate studies [illegible] college curriculum may follow the same plan, and [illegible] for original research along those lines in which [illegible] may be eminent authorities. However, [illegible] is that when one enthusiastic instructor [illegible] place, the new occupant of the professor[illegible] already given his leisure time to some one of the [illegible] groups of the animal kingdom entirely different from [illegible] by his predecessor, and the books and specimens he finds already gathered will prove of little value to him for the pursuit of his own favourite branch of our science.

MUSEUMS AS EDUCATORS.

"A museum of natural history developed by a distinct corporation may advance education in two different ways—firstly, by the exhibitions of its collections and by illustrated lectures; and, secondly, by securing such exhaustive series of specimens and the books treating of them as to render it possible for original research to be carried on in many or most of the orders of the animal kingdom. Such organisations could favourably utilise an unlimited amount of funds, and even partly to fulfil their mission must absorb enormous sums. They can, therefore, only be created in our great and wealthy cities, and in them only by a happy and enthusiastic co-operation of their State and Municipal Governments, supplemented by large gifts from their wealthiest and most generous citizens. Our museum in Central Park is becoming such an institution for instruction and investigation. The city has provided a site of eighteen acres and $2,500,000 for that part of the structure already erected and under contract. Our specimens and books, the gifts of private citizens, amount to about $2,000,000 more, and yet we have completed less than one-fifth of our proposed edifice. The Art Museum has even a larger property and as comprehensive a plan, and now the Lenox and Astor Libraries, and the Tilden gift are happily united, and together form a third stone in the arch of this central university for the highest culture. So that, while we visit London to admire its group of noble institutions at South Kensington, we are at the same time founding in our new land a similar series on a greater scale, and erecting buildings and accumulating collections at a rate not witnessed on the other side of the sea; but the extensive ground plan upon which we are building the Museum of Natural History embodies the views of the late Sir Richard Owen, the ablest investigator in our science of the present century.

"In such a museum the specimens of minerals, rocks, and even fossils may be nearly perfect in themselves or fairly representative of the formations from which they were taken, but it should be remembered that in the usual mode of exhibition of animals and plants we necessarily lose the charm of their environment. Thus the song-thrush, which in life fills these northern valleys with the magical music of its liquid notes, when mounted and placed in a case is not only mute but uninteresting. The humming birds, in all their array of brilliant gems, to be known must be seen alive, darting to and fro amid the fragrant and richly-coloured flowers which supply their food in the tropical lands where the stately palm-trees wave their graceful fronds. The albatross, as usually mounted, with its wings tamely folded, hardly suggests the noble bird that skims gleefully over the crests of mountainous waves, while the storms are raging in the 'Roaring Forties' of the southern ocean. The chamois can only be appreciated when it is seen aloft on some projecting crag of the Alps, and the Rocky Mountain goat when, after long climbing, we find it surrounded by the splintered peaks of the Selkirks high up on the borders of eternal ice.

"To remedy these defects such a progressive thinker as Sir William Flower wisely proposes an entire change in the present style of taxidermy, and our experience in New York has been that our cases of American birds in their native haunts are among the most attractive as well as instructive displays in our halls. In our illustrated lectures we exhibit on one screen the Rocky Mountain sheep, while we picture on another screen beside it the grand mountain of the Holy Cross, where this rare animal formerly roamed.

"Zoology has attained a prominent place in this country largely through that great investigator and instructor, Prof. Lewis Agassiz, whose marvellous store of knowledge was equalled only by his devotion to his favourite study.

"But while science should be pursued for science's sake, yet we must not under-estimate the value of the technical sciences which take the results of original research and transform them so that they may confer an immediate and practical benefit upon the whole world. It is in this great department of modern education—the applied sciences—that the American people are pre-eminently successful, and in the coming contest for the supremacy among all nations, ours is destined to maintain a commanding place through our untiring industry, inventive genius, and peculiar adaptability to meet new conditions."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Prof. J. W. Judd, C.B., F.R.S., has been appointed Dean of the Royal College of Science, in succession to the late Prof. Huxley.

The following list of Royal scholarships, medals, and prizes awarded last month in connection with the Royal College of Science, London, has just been issued by the Department of Science and Art. Royal scholarships: First year's Royal scholarships, Ernest Smith, George Marks Russell, Frank Fisher, Norton Baron; second year's Royal scholarships, Robert Sowter, Joe Crowther. Medals and prizes:—"Edward Forbes" medal and prize of books for Biology, William George Freeman; "Murchison" medal and prize of books for Geology, John Caspell; "Tyndall" prize of books for Physics, Part I., William Herbert White; "De la Beche" medal for Mining, Robert William Pringle; "Bessemer" medal and prize of books for Metallurgy, John Collet Moulden; "Frank Hatton" prize of books for Chemistry, William Longshaw. Prizes of books given by the Department of Science and Art:—Mechanics, Cecil Alwyne Selpram Baxter; Astronomical Physics, Ernest Edward Leslie Dixon, William Herbert White; Practical Chemistry, Henry William Hutchin; Mining, Robert William Pringle; Principles of Agriculture, William Williams.

The University of Pennsylvania has issued an appeal (says *Science*) asking for an endowment fund of £1,000,000 to meet the immediate requirements of the University. Mr. Thomas McKean has given without restrictions a sum of £10,000 in addition to the £10,000 given a few months ago. A contribution of £2000 has also been received from Mr. Richard F. Loper. It is stated that this is the thirteenth contribution of a similar kind that has been received. We learn from the same source that the University of Cincinnati has received a gift of £9000 from Mr. Henry Hanna, to be used in the erection of a wing in the new University building.

SOCIETIES AND ACADEMIES.

Dublin.

Royal Dublin Society, April 24.—Prof. J. Mallet Purser in the chair. The following communications were read: Dr. E. J. M'Weeney on a temporary variation in the quality of the Vartry water. [This is the water-supply of the city of Dublin.]—Dr. David Hepburn (of Edinburgh), on the papillary ridges on the hands and feet of monkeys and men. The material for this paper was supplied by the anthropological laboratory of Trinity College, Dublin, and the paper was communicated by Prof. D. J. Cunningham, F.R.S.—Mr. Walter E. Adeney, on the course and nature of fermentative changes in natural and polluted waters, and in artificial solutions, as indicated by the composition of the gases in solution.

May 22.—Mr. Thomas Preston in the chair. The following communications were presented: Prof. Emerson Reynolds, F.R.S., note on the spectrum of argon.—Mr. W. E. Adeney, on the chemical examination of organic matters in river water.—Mr. Richard J. Moss, on the preparation of helium.—Mr. Moss also exhibited a simple form of apparatus for the distillation of mercury in vacuo; and Dr. W. Frazer showed some photographs of the natives of Formosa.

June 20.—Dr. J. Joly, F.R.S., in the chair. The following papers were read: Mr. Thomas Preston, on the rectilinear propagation of light. Dr. J. Joly, on photography in natural colours.—Sir J. William Dawson, F.R.S., note on a paper on "Eozoonal structure of the ejected blocks of Monte Somma," by Dr. H. J. Johnston-Lavis and Dr. J. W. Gregory, and reply to the note by the last-named authors.—Dr. G. Johnstone Stoney, F.R.S., criticism of the kinetic theory of gases regarded as illustrating nature. Dr. E. J. M'Weeney, further observations on the Vartry water. Dr. M'Weeney exhibited cultivations of *Phoma Betae*, a fungus that produces a disease of the mangold wurzel.

Paris.

Academy of Sciences, July 29.—M. Marey in the chair.—On the presence of water vapour in the atmosphere of the planet Mars, by M. J. Janssen. Mr. W. W. Campbell has recently asserted that the atmosphere of Mars does not contain water vapour, and has requested further details concerning the author's observations, from which the presence of water vapour had been supposed to be proved. These details are now supplied; the author particularly points out that his Etna observations were carried out under exceptionally favourable conditions, and that the definite and convincing evidence they afforded was confirmed by observations carried out at Palermo and at Marseilles.—On groups of substitutions of the same order and degree, by M. Levavasseur.—On algebraical surfaces admitting of a continuous group of internal birational transformations, by MM. G. Castelnuovo and F. Enriques.—On algebraical machines, by M. Léonardo Torres.—Vibrations of the tuning-fork in a magnetic field, by M. Maurain.—New photographs of lightning flashes, by M. N. Piltschikoff. Several types of lightning flash are defined, and the dimensions are given for certain flashes; for instance, a photograph taken during a storm at Odessa on June 13, shows a luminous band 0·75 mm. wide, caused by a flash at a greater distance than 10 kilometres; the actual width of the flash was therefore more than 62 metres.—A new voltaic cell, by M. Morisot. The cell consists of a carbon pole immersed in 1 : 4 sulphuric acid saturated with potassium bichromate and a zinc pole within a porous cell containing concentrated caustic soda solution (sp. gr. 1·25), this cell being separated from the depolarising acid solution by a second larger porous cell containing dilute caustic soda (sp. gr. 1·05). The E.M.F. of this cell is to begin with 2·5 volts, and remains above 2·4 volts during at least ten hours of uninterrupted action, and with variable external resistance remains constant. The intermediate bath of dilute alkali diminishes the action across the porous diaphragm between the soda and the sulphuric and chromic acids without materially increasing the resistance. The zinc is less attacked than with an acid bath, and may readily be brought into good condition after long use by a short immersion in acid.—Action of aniline on mercurous iodide, by M. Maurice François. The aniline decomposes the mercurous iodide with the formation of the substance diphenylmercurodiammonium iodide $(C_6H_5NH_2)_2HgI_2$, and metallic mercury. The reaction is incomplete and exactly similar to the action of water on bismuth sulphate or mercuric sulphate. The boiling saturated aniline solution dissolves mercurous iodide and redeposits it on cooling in the crystalline form.—Action of nitric peroxide on campholenic acid, by MM. A. Behal and Blaise.—On the products of the condensation of isovaleric aldehyde, by M. L. Kohn.—On the estimation of boric acid, by MM. H. Jay and Dupasquier. The boric acid is distilled over into soda by the aid of methyl alcohol used continuously and the residual soda determined by titration.—On the elimination of lime among those affected with rickets, by M. Oechsner de Coninck.—On the utility of injections of oxysparteine before anæsthesia by means of chloroform, by MM. P. Langlois and G. Maurange. The injection, an hour before the operation, of 4 to 5 cgr. of sparteine or 3 to 4 cgr. of oxysparteine, together with 1 cgr. of morphine, gave rapid narcosis easily maintained with little chloroform and a regular pulse, energetic even when the respiration became superficial.—Influence of toxines on progeny, by M. A. Charrin. Bacterial poisons derived from the mother, like those introduced otherwise into the system, retard the growth of infants by rendering assimilation less perfect.—On the structure of the ectoderm and of the nervous system of parasitic Plathelminthes (Trematodes et Cestodes), by M. Léon Jammes.—Contributions to the embryogeny of simple Ascidians, by M. Antoine Pizon.—On the composition of the monazite sands of Carolina, by M. Boudouard.—Discovery of gigantic remains of fossil elephants, made by M. Le Blanc, in "la ballastière de Tilloux (Charente)," by M. Marcellin Boule.

Berlin.

Physical Society, June 14.—Prof. du Bois Reymond, President, in the chair.—Dr. F. Kurlbaum gave an account of his determination of the unit of light made in conjunction with Prof. Lummer. The unit was based on the light emitted by white-hot platinum foil. Since the radiant energy varies with the temperature, it was necessary to keep the latter constant for a prolonged period, and to be able to re-establish it at any time. This result was arrived at bolometrically by measuring the ratio of the total radiant energy from the glowing foil to the radiation taking place across an absorbing medium. This ratio is dependent upon the temperature of the radiating body, and provides a trustworthy measure of its temperature. It was necessary to find some covering for the bolometer which should absorb all rays as uniformly as possible; after many experiments a layer of

platinum black was found most suitable for this purpose. The absorbing medium employed consisted of a thin layer of water in a quartz cell. The energy radiated from the heated foil passed through a diaphragm of known aperture, whose temperature was the same as that of the bolometer. The errors in determining the unit of light amounted to one per cent., due chiefly to the air currents on the surface of the foil. The unit can now be established at any time in the Imperial Physico-technical Institute (Berlin); but in order to facilitate its accurate establishment at any other place, experiments are being made to determine the temperature of the glowing foil from ratio of the radiation over the range of the visible spectrum.

June 28.—Prof. von Bezold, President, in the chair.—Dr. Kaps exhibited and described some new electric meters constructed by Siemens and Halske, which by the use of constant magnets provide an accurate measure for technical purposes, and are uninfluenced by ordinary variations of temperature. Dr. du Bois described experiments made by Dr. E. T. Jones on magnetic lifting-power. He had already showed that Maxwell's formula holds good for a field whose strength is up to 500 C.G.S., and now passed on to fields of greater strength. In the last set of experiments electro-magnets were employed with a sectional surface of an iron bar passed through the armatures. A magnetic lifting power of 52 kilogrammes per square centimetre of surface was thus for the first time obtained, and Maxwell's formula was found to hold good up to this maximal value; the error was at most five per cent., due as yet to insufficient introduction of corrections. Stephan's formula did not in any way correspond with the results of the above experiments. It further appeared that a lifting power of 150 kilogrammes per square centimetre should be obtainable.

Amsterdam.

Royal Academy of Sciences, June 29.—Prof. Van der Waals in the chair. Prof. Martin presented a work, written by him, and entitled "Die Fossilien von Java." Basing his arguments on the presence of these fossils, the author showed that in Java there are found Upper Miocene, Pliocene and Quaternary sediments. When the distribution of these formations is considered, it appears that in general the newer strata have been formed on the outer side of the older ones, and there can be no doubt that since the time of the Upper Miocene formation a continuous and very slow elevation of the coast ("negativ strandverschiebung") took place, in consequence of which the Upper Miocene, Pliocene and Quaternary sediments of the coast were laid dry. That this shifting of the coast was very considerable, is proved by the Njaliendoeng fossils, found 910 m. above the level of the sea, and this fact further tallies with what is known about Sumatra, where in the "Padangsche Bovenlanden" Neogene sediments have been found up to a height of 1088 m. Not long ago the author showed that during the Quaternary period a considerable movement took place in the eastern part of the archipelago, and numerous facts show that the whole of the Indian archipelago was subjected to this. The author further remarked that he had received interesting fossils from Western Borneo. Among them are: *Perisphinctes* (Waag.), *Pecten* [illegible], and *Corbula*. All these fossils have been found in strata that were formerly known as "ancient schists," which, however, on account of the above-mentioned fossils, can only be reckoned to belong to the Mesozoic period; more particularly they ought to be classed either with the Jurassic or with the Cretaceous formation. In accordance with the present state of our knowledge it is highly probable that the fossils in question have been taken from Jurassic formations. It appears, then, that Mesozoic strata have a very wide distribution in the Indian archipelago. Prof. [illegible] read a paper on *Cynips calyx*. The *Cynips calyx* gall, very common in Austria Hungary on *Quercus pedunculata*, [illegible] in commerce as a first-rate tanning material. In [illegible] Netherlands two or three small localities are known where [illegible] to be found. The dehydration, rehydration and re-[illegible] of colloidal silicic acid, by Prof. van Bemmelen. [illegible] presented some pamphlets by himself and some of [illegible], with reference to Dr. Langemeyer's dissertation, [illegible] the influence of the use of sugar upon muscular labour. [illegible] experiments, made with the ergograph, it is deduced that [illegible] in this way been proved that sugar has a favourable [illegible] muscular labour.—At the request of Dr. C. A. Lobry de Bruyn, Prof. Franchimont communicated that free hydrazine had been prepared by the former in two ways: 1° from N_2H_4HCl with sodium methylate in a methyl alcoholic solution, and 2° by heating the hydrate to 100° with barium oxide. Free hydrazine is a somewhat thick fluid with the smell of the hydrate. It boils without decomposition at 113°·5 and a pressure of 761 m.m., and at 56° if the pressure is 71 m.m. When cooled, it becomes solid, and then melts again at 2°; its density at 23° is 1·0075 and does not, therefore, differ much from that of the hydrate (boiling at 119°). In ordinary air it forms strong vapours and is easily oxidised by oxygen with the formation of nitrogen. In the air it will burn, but not explode, like hydroxylamine, and consequently it is much more stable.—Prof. Kamerlingh Onnes communicated measurements on the capillarity of liquid gases, made by Dr. Verschaffelt in the Leyden laboratory. Carbonic acid and nitrous oxide obey the law of corresponding states; their capillary equation has an exponent approaching the theoretical value given by Van der Waals, and they are not associated fluids.—Prof. Van der Waals presented a paper intended for the report of the meeting, and entitled: "On the critical circumstances of a mixture," being a sequel to what was communicated in the meeting of the section held in May.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Bouches à Feu: E. Hennebert (Paris, Gauthier-Villars).—Balistique Extérieure: E. Vallier (Paris, Gauthier-Villars).—Geological Survey of Canada, Annual Report, new series, Vol. 6 (Ottawa).—Science Readers, Book iv.: V. T. Murché (Macmillan).—A Text-book of the Principles of Physics: Dr. A. Daniell, 3rd edition (Macmillan).—Pan-Gnosticism: N. Winter (Transatlantic Publishing Company).—A Handbook to the Flora of Ceylon: Dr. H. Trimen, Part ; and plates (Dulau).

Pamphlets.—Gegenetische Beitrage: Dr. O. Kuntze (Leipzig, Gressner).—Sobre Peces de Agua Dulce: C. Berg (Buenos Aires, Alsina).—The Grimsby Trawl Fishery, &c.: E. W. L. Holt (Plymouth).

Serials.—Journal of the Institution of Electrical Engineers, July (Spon).—Quarterly Journal of the Geological Society, August (Longmans).—Fortnightly Review, August (Chapman).—Macmillan's Magazine, August (Macmillan).—Scribner's Magazine, August (Low).—Verhandlungen des Naturhistorischen Vereins, &c., Einundfünfzigster Jahrg., Sechste Folge, 1 Jahrg., Zweite Hälfte (Bonn).—Bulletins de la Société D'Anthropologie de Paris, tome vi. 4e serie (Paris, Masson).—Geological Magazine, August (Dulau).—Geographical Magazine, August (Stanford).—Transactions and Proceedings of the New Zealand Institute, 1894, Vol. xxvii. THURSDAY, AUGUST 15, 1895.

THE HISTORY OF EVOLUTION.

From the Greeks to Darwin: an Outline of the Development of the Evolution Idea. By Henry Fairfield Osborn, Sc.D., Da Costa Professor of Biology in Columbia College, &c. (New York: Macmillan and Co.

THE object of this most interesting and useful work is to survey the last twenty-four centuries and bring together the thoughts—true and false—upon evolution. Examining and comparing the material which he has collected, the author concludes "that the influences of early upon later thought are greater than has been believed, that Darwin owes more even to the Greeks than we have ever recognised." In supporting this conclusion the author desires to give due credit to the earlier writers, but not to lower in any way the transcendant position occupied by Darwin. Indeed, so scrupulously fair is the treatment that the materials are thoroughly available to those who do not altogether follow the author in his conclusion. And many objections to the conclusion are most prominently brought forward. Thus the great interval between the beginning and the middle of the present century, when all continuity in evolutionary thought seemed to be broken, is described again and again. We read on page 12: "Perhaps the sharpest transition was at the close of the third period, in which a distinct anti-evolution school had sprung up and succeeded in firmly entrenching itself, so that Darwin and Wallace began the present era with some abruptness." Again, on pages 227 and 228, the strong prejudice against evolution which marks this period is illustrated in many ways, and the section concludes: ". . . all the progress which had been made in the long centuries we have been considering was, for the time, a latent force. The Evolution idea, with the numerous truths which had accumulated about it, was again almost wholly subordinate to the Special Creation idea."

The recognition of this strongly-marked gap in the history of evolutionary thought, and, above all, the details which we learn from Darwin's "Life and Letters," tend to throw doubt upon the view that he drew much of his inspiration from the past. The great majority of naturalists could not entertain the idea of evolution unless some explanation of its cause was forthcoming. Darwin treated the process and the cause as entirely distinct, and was convinced of the one long before he had come to any definite opinion about the other. In accepting evolution as against special creation, we fail to find any evidence that Darwin was influenced by the arguments or conclusions of an earlier day. He was influenced and finally convinced by his conclusions from his own observations on the *Beagle* (quoted by Prof. Osborn on p. 233). In looking for the causes of evolution he was equally independent of the past; for he saw that adaptation was the central fact which required explanation, and which had received none at the hands of the naturalists with whose writings he was acquainted.

But whether the thread be broken or continuous, the history of thought upon this all-important subject is of the deepest interest, and Prof. Osborn's work will be welcomed by all who take an intelligent interest in evolution. Up to the present, the pre-Darwinian evolutionists have been for the most part considered singly, the claims of particular naturalists being urged often with too warm an enthusiasm. Prof. Osborn has undertaken a more comprehensive work, and with well-balanced judgment assigns a place to every writer.

The history of thought upon evolution from 640 B.C. to the present day is divided into two main phases, the second of which is further subdivided into three periods.

The first phase, "The Anticipation of Nature: Greek Evolution," and its effects on Christian Theology and Arabic Philosophy, lasted from 640 B.C. to 1600 A.D.

The second phase, "The Interpretation of Nature: Modern Evolution," opens with the period of "Philosophical Evolution," from 1600 to 1800, associated with the names of Bacon, Kant, Herder, Bonnet, Oken, &c. In this period the Greek traditions were largely shaken off, and inductive evolution began.

The next period, that of the rise and decline of "Modern Inductive Evolution," somewhat overlapping the last, is limited by the years 1730 and 1850, from Buffon to St. Hilaire. It depends upon the writings of Linnæus, Erasmus Darwin, Lamarck, Goethe, Treviranus, &c. At the close of this period, Owen and Herbert Spencer are placed.

The last period, that of the re-establishment of "Modern Inductive Evolution" upon a firmer foundation, dates from 1858 to the present day. It is associated with the names of Darwin and Wallace, and marked by the scientific evidences of evolution, by the theory of natural selection, by observation and speculation upon other factors of evolution.

The section which deals with the Greeks has been somewhat unfairly criticised. Some people appear to believe that an account of Greek ideas upon evolution can only be attempted with success by an eminent classical scholar. But classical scholars have already done their utmost in the way of translation and of study. It is now of far greater importance to have a critical account, like that in the work we are considering, by a writer who is an authority upon evolution.

In discussing "The Legacy of the Greeks" (pp. 64–68) the author points out that the first element is "scientific curiosity, their desire to find a natural explanation for the origin and existence of things." The complete dependence of all investigation upon this spirit is maintained, and it is truly said that "the ground motive in science is a high order of curiosity, led on by ambition to overcome obstacles." The final conclusion is that "the Greeks left the later world face to face with the problem of causation in three forms: first, whether intelligent design is constantly operating in nature; second, whether nature is under the operation of natural causes originally implanted by intelligent design; and third, whether nature is under the operation of natural causes due from the beginning to the laws of chance, and containing no evidences of design, even in their origin."

In this section of the work we find, as we might expect, that the genius of Aristotle completely overshadows that of the other Greek writers who attempted to face the problems of the origin and development of living forms.

R

In the long second period, that of the theologians and natural philosophers, "no advance whatever in the development of the evolution idea was made . . .; scientific speculation and observation were at a standstill, except among the Arabs" (p. 70).

As we advance towards the work of the naturalists and philosophers of the two last centuries, the difficulties and dangers of interpretation increase. It is even easier to read preconceived notions into the single passages of dead writers than into the phenomena of nature; and we all know that the latter process is only too easy. If the results are not to be in the highest degree misleading, the author must, like Prof. Osborn, be entirely free from bias, and must possess a cool and critical judgment.

We meet with constant and timely protests against the rash conclusions which may be reached by selecting isolated passages from an author, and dealing with them apart from their context, and the full recognition of the great danger which underlies this too common practice, viz. that we unconsciously read into such passages our present knowledge (p. 80).

Prof. Osborn considers that too high a place has been assigned to Oken and Treviranus by Haeckel and Huxley respectively, and that Naudin's supposed anticipation of natural selection is far from being as satisfactory as Quatrefages and Varigny maintain. The suggestion that Oken anticipated the cell theory is acutely criticised: it is suggested that his conception of the cell as a sphere was probably only a result of the transcendant position occupied by this geometrical form in his system of philosophy (p. 124).

The suggestion (on p. 235) that Darwin's 1844 Essay should be published will, the present writer feels assured, meet with warm approval from the wide circle of readers who are eager to learn all that can be learnt of the history of Darwin's views upon the great work of his life.

The hope is expressed (on p. 245) that we shall learn the steps which led to Wallace's independent discovery of natural selection. That information is fortunately now before us, and we know that Wallace was led to the discovery by reflecting on Malthus' "Essay on Population," as he lay ill of intermittent fever at Ternate (quoted, without reference, in Milnes Marshall's "Lectures on the Darwinian Theory," London, 1894, pp. 212, 213, and to be found in the abridged form of the "Life and Letters of Charles Darwin"). Thus another most important detail is added to the extraordinary coincidence of the independent discovery of natural selection.

There is comparatively little to criticise in the volume. The idea of the marine origin of life, traced to Thales, is stated to be "now a fundamental principle of evolution" (p. 33): but at the end of the volume it is more correctly asserted that we are now too wise to answer the query, "Where did life first appear?" (p. 247).

Concerning the debated question as to whether Lamarck was aware of Erasmus Darwin's writings, and made use of them without acknowledgment, the author (pp. 154, 155) quotes a passage from the "Animaux sans Vertèbres," in which Lamarck states that his theory is the first which has been presented. This he considers to be "satisfactory evidence that Erasmus Darwin and Lamarck independently evolved their views." But if Lamarck borrowed without acknowledgment, it would be but a small step further to write the passage in question.

The statements and conclusions to which exception is chiefly to be taken concern the life of Darwin himself, which the author professedly treats in a very brief and imperfect manner, any detailed account being beyond the scope of this volume.

The author speaks (p. 227) of "Huxley's somewhat guarded acceptance of the theory" on the first appearance of the "Origin," and implies that he became a much stronger supporter of evolution in later years. But in reality his convictions on this subject never changed. In his letter to Darwin, written November 23, 1859, the day before the publication of the "Origin," Huxley expressed himself as "prepared to go to the stake, if requisite, in support of" those parts of the book which deal with evolution as apart from natural selection. As to the latter he says: "I think you have demonstrated a true cause for the production of species, and have thrown the *onus probandi* that species did not arise in the way you suppose, on your adversaries." And these were Huxley's views up to the last occasions on which he spoke on the subject, at the Oxford meeting of the British Association last year, and at the anniversary of the Royal Society when he received the Darwin Medal. On both occasions he carefully distinguished between evolution and natural selection, being prepared to defend the former to the uttermost, while he declined to commit himself upon the latter.

It is contended (p. 239) that Darwin's faith in natural selection reached its climax in 1858, and then gradually declined. The evidence quoted in support of this conclusion is a letter to Carus in 1869, in which Darwin says: "I have been led to infer that single variations are of even less importance in comparison with individual differences than I formerly thought." But this passage proves a strengthening, and not a weakening of his belief in the efficiency of natural selection, inasmuch as it is considered competent to work upon the minute differences which separate individuals instead of upon the ready-made material provided by single variations, however conspicuous. By "single variations" he meant single individuals differing widely and conspicuously from the average of their species. His letter to Carus was written shortly after he had been convinced on this point by Fleeming Jenkin's review of the "Origin" (*North British Review*, June 1867). A careful study of vol. iii. of the "Life and Letters" leaves no doubt upon this point; while the facts thus brought out tend to refute the argument on p. 245 as to the supposed antagonism between Darwin's and Wallace's conception of the operation of natural selection as expressed in their contributions to the Linnean Society in 1858.

A passage in the sixth edition of the "Origin" is referred to (p. 242) as having been published in 1880, and is therefore considered to be "among Darwin's last words upon the factors of evolution." The passage in question is referred to p. 424 of the "Origin," but occurs on p. 421 of the copies I have consulted. In it Darwin expresses his belief that evolution has been effected "chiefly" by natural selection, "aided in an important manner by the inherited effects of use and disuse of parts; and in an

unimportant manner . . . by the direct action of external conditions . . ." This passage is considered by Osborn to prove that the progressive tendency towards the explanations of Lamarck and Buffon which he believes Darwin exhibited from 1859 onwards culminated at the close of his life. But the sixth edition appeared in 1872, and the date 1880 is merely that of a reprint. The words in question were certainly written before the former date, and even in the fifth edition (1869) Darwin inserted the word "chiefly" to qualify an expression of confidence which might have been interpreted as a belief in the all-sufficiency of natural selection.

The fact appears to be that there was no progressive change in Darwin's attitude on this subject, but that his opinion fluctuated as various classes of evidence were brought before him, and at the very end of his life his belief in the direct action of external conditions was seriously shaken by the results of Hoffmann's experiments. The effect produced on him is well shown in his letter to Semper, written July 19, 1881, less than a year before his death ("Life and Letters," vol. iii.). But although Darwin's opinion fluctuated as to the relative value of the supposed causes of evolution other than natural selection, his views as to the paramount importance of the latter never varied in any of his published utterances. The words which conclude the Introduction of the 1859 "Origin" are repeated without change in each succeeding edition and reprint. "Furthermore, I am convinced that natural selection has been the main, but not the exclusive means of modification."

The printing and general get-up of this interesting work leaves nothing to be desired, being far above the average that obtains in scientific publications. It may confidently be predicted that the book will be widely read and greatly appreciated. E. B. P.

THE ELEMENTS OF ARCHITECTURE.

Architecture for General Readers, &c. By H. Heathcote Statham. 8vo. London: Chapman and Hall, 1895.

THE aim of this treatise, as stated in the preface, is certainly a good one, namely, to supply the "general reader" with the means of criticising architecture in an intelligent manner, and principally by giving an analysis of the two most logical and complete styles that have ever existed, namely, the Greek and the Gothic; the former representing the trabeated, and the latter the arcuate system of building. Our author, however, very properly does not confine his attention to these two styles and their later developments, but also makes wide digressions in the direction of Egyptian, Byzantine, and Mahommedan structures, all of them being copiously illustrated and discussed at considerable length. The work exhibits throughout the author's great and varied acquaintance with his subject, and cannot but be of much interest and value to any reader who desires to dive more deeply than amateurs are accustomed to do into the principles which ought to guide the professional architect, and which, indeed, do guide all those who achieve anything worthy of the art in which they practise.

In page 20 the importance of planning is properly insisted on. The plan is shown to be the very "backbone" of the structure, and the attention of the "general reader" is rightly called to this. It may be doubted, however, whether the general reader is prepared for the minute criticism, which we find a little further on, respecting certain competition designs, which criticism is rendered the more difficult to follow, in consequence of the small scale of the plans by which these designs are illustrated, and he may, perhaps, wish that he had been led into such deep water more gently. In page 31, with reference to the proportions of buildings as affecting the eye, the author appears to doubt whether (with the exception of the late Mr. W. W. Lloyd's discovery of the system which prevails in the Parthenon) any definite and clear case has been made out for the establishment of proportion theories. The author is probably quite justified in his refusal to accept any general adoption of a system for proportioning buildings "on the basis of geometrical figures, especially triangles of various angles." There could not possibly be any æsthetic value in confining the main lines of the architecture within such limits; but rectangular proportions in low numbers (of which nature are the proportions of the Parthenon) are on a different footing, and it is extremely probable that they do produce harmonious effects. They are to be found in many other Greek examples besides the Parthenon, and in one Gothic building at least, namely, the work of Bishop Grosetete in the nave of Lincoln Cathedral (see the *Transactions* of the Archæological Institute of Great Britain, &c., for 1848), where rectangular proportions of this character come out without any "coaxing" with remarkable exactness; and as Bishop Grosetete, besides being a great ecclesiastic, was one of the most prominent philosophers of his day, there is the more reason to accept it as having been intentional.

In p. 34, the chief characteristics of the Egyptian, the Greek and the Gothic are summed up in a few words, as Mystery, Rationalism, and Aspiration. In p. 43, the meed of merited praise is given to Mr. E. L. Garbett's excellent little treatise on "The Principles of Design in Architecture." In p. 58, doubt is thrown on the wooden origin of the Greek entablature. The reader, however, may be referred to MM. Perrot and Chipiez' recent work on "The Arts of Primitive Greece," in which this derivation is shown from the remains at Tiryns, Mycenæ, and Orchomenus. In p. 73, the Corinthian example of the temple of Jupiter Olympius at Athens should not be attributed to a Roman source; it dates from Antiochus Epiphanes, the Greek founder, and the prototype of the capital is found in the *tholos* at Epidaurus, a pure Greek building. No doubt at the time the Athenian temple was built, about 170 B.C., Rome was pushing her way towards the East, and Antiochus himself had been sent as a hostage to Rome after the defeat of his father by Scipio. There may have been something political in his employment, as we are told of a Roman citizen as his architect, but the architecture itself, at that date, could not but have been thoroughly Greek.

In p. 78, the author well illustrates his argument, showing the superiority of constructive simplicity in a design over another decorated with meaningless architectural detail, by the contrast of London and Blackfriars Bridges; but it is not so clear, as maintained in the previous page that the combination of columnar and arcuate design in the same wall is a "Roman sham." It is no doubt a

departure from primitive simplicity, but there seems no reason for calling it a sham, in cases where both types are used constructively. The "general reader" may certainly be justified in passing over the "approximate theory" of the strains of arches, but the subject of pendentives (in p. 95) is more to the point, having very important relation to the construction of cupolas. Much more seems to be made in the criticism on the shams of St. Paul's (p. 98) than the subject warrants. The design is blamed because the interior cupola is distinct from the external. There would be as much reason to blame the magnificent central towers of some of our cathedrals because the open lantern chamber over the crossing does not rise to the summit of the tower or spire. The author, however, duly praises Sir Christopher Wren's first design, the Greek cross plan, of which a good judge, the late Rev. J. L. Petit, has maintained that if this design had been executed it would have been the finest interior in the world. On the subject of vaulting (pp. 107–116), the development of which is well and clearly followed out, it is stated that the pointed arch was *invented* for the purpose of facilitating the construction. This could hardly have been the case, because the pointed arch had been used in the East long before the period referred to; but its great applicability to that favourite architectural feature was then recognised, and when once introduced for constructive reasons, it soon began to influence the whole structure.

In p. 125 commences a chapter on the theory and use of mouldings, which play so important a part in architectural design that it is quite essential that an amateur who desires to form a right judgment on architectural subjects, either historically or critically, should study their development and application; he will find the subject clearly and logically explained in this chapter. In chapter v. are some judicious remarks on ornament, showing on the one hand that however valuable a help it may be, the art is really independent both of sculpture and carved ornament, and that the latter is inferior in expression to mouldings properly used. In pp. 184–188 are some just views on the combination of architecture with scenery. Without going so far as to say that a spire on a hill—such, for instance, as Harrow—must necessarily be ill-placed, the statement of the incongruity of this feature in a mountainous country may be supported by citing the example of incongruous effect of the Ambleside spire in a Westmoreland valley.

The work ends with an historical sketch, which shows much thought and learning. The author can, however, scarcely be correct in speaking of such structures as the Treasury of Atreus at Mycenæ as formed of large blocks of masonry with no architectural details whatever. It is possible that the ornate elaboration of the Beehive tombs at Mycenæ and Orchomenus, as shown in Perrot and Chipiez' work, before referred to, may be a good deal exaggerated; but there certainly exists evidence for a very considerable amount of architectural embellishment. In speaking of the derivation of the Corinthian capital, it seems unnecessary, with the small amount of evidence to the contrary which exists, to relegate to the regions of fable the touching little story told by Vitruvius (chapter iv. p. 1[illegible]) of its invention by Callimachus, especially as the earliest known example, in the temple at Bassæ, was the work of a contemporary, and probably a friend of the reputed inventor.

In p. 255 the very important derivation of the dome is traced from the Pantheon, of which the date (in the reign of Hadrian) has lately been established, and then the addition of the spherical pendentive by Justinian's architect (Anthemius of Tralles) in the great church of St. Sophia. To this is added the derivation of the architecture of the Western churches—which is traced—following Prof. Baldwin Brown ("from the Schola to Cathedral"); from the Roman house, of which the atrium and peristylium became the forecourt or parvis and the porch, whilst the basilica supplied the apse, and the widening of the basilica on each side of the tribunal gave the germ of the transepts of our cathedrals. In the summary of the different contributions made by the European nations to Gothic architecture, Italy is denied altogether a specimen of true Gothic—and yet it possesses in Milan Cathedral an interior perhaps more impressive than that of any other church.

"PARTURIUNT MONTES."

The Story of the Plants. By Grant Allen. (London: George Newnes, Limited, 1895.)

MR. GRANT ALLEN tells the story of plants in a readable and very inaccurate manner. The keynote to his work is struck in his preface, in which he informs his reader that he has "wasted comparatively little space on mere structural detail," and, later on, that he makes "trivial sacrifices of formal accuracy" in order to expound general biological relationships. It is true that he apologises for these amiable little weaknesses, but adds, in the same breath, that he lays before his "untechnical readers all the latest results of the most advanced botanical research." It is impossible to avoid giving some samples of these "latest results."

For Mr. Grant Allen, the plant is essentially the *green* plant, and the essential function of this plant is constructive metabolism. On the other hand the animal is the very opposite of this, "he is a destroyer, as the plant is a builder." But we fancy most people will hardly admit this antithesis nowadays. Plants and animals both exist by breaking down complex bodies to simple ones, but plants as a whole can get the energy required for first building up these complex bodies at a less expensive outlay than animals, and the green plants, as Mr. Allen perfectly correctly observes, are further able to make use of sources of energy (*i.e.* vibrations of ether) from which their less fortunate relatives are debarred. But to draw the distinction just quoted as the *essential* difference between the two kingdoms, is obviously misleading. However, Mr. Allen is at least consistent in his views, since he states that the first plants "must have been green."

In the account given of the *modus operandi* of the building up of organic matter in the plant, the author's claims to up-to-date knowledge will, we fear, hardly be admitted. Chlorophyll is said to be the active agent in splitting up (under the influence of sunlight) the carbon dioxide and water to form starch. Now every student knows that chlorophyll can do no such thing, and further he knows, or should know, that starch is certainly not a primary product of assimilation. The latter, perhaps,

is a "trivial detail," but Mr. Allen hastens to insist on the importance of "living chlorophyll" as the "original manufacturer and prime maker" of all the material of life, either vegetable or animal. Evidently chlorophyll is here doing duty for the alliance of chlorophyll with a vastly more important substance, protoplasm, but the author could hardly expect "untechnical readers" to appreciate this; and his statement that chlorophyll is a variety of protoplasm will certainly not meet with the assent of botanists. Again, the statement that "plants alone know how to make protoplasm" is one which is contradicted, fortunately for us all, by the experience of daily life; in order, however, that we may be quite clear as to the author's conception of protoplasm, he defines it (in italics) as "*the only living material we know*"; and this would seem to make it clear that he had not by a *lapsus calami* written protoplasm when he meant proteid. For a continuation of this subject, the critical reader may refer to pp. 190-191.

When Mr. Allen comes to deal with what we gather from his preface he considers the most important part of his work, we find evidences of hasty generalisations on insufficiently ascertained facts. Many plants which are certainly not degenerate, are regularly self-fertilised; and we submit that in most districts in England the humble bee has far more to do with the fertilisation of the Tropæolum than the Humming-bird hawk-moth; and this latter insect is certainly *not* the only one in Europe capable of performing this office.

But it is needless to multiply examples further. All we can say is that those readers who are ignorant of the real facts may find the book pleasant, though we can hardly add profitable, reading.

OUR BOOK SHELF.

Low's Chemical Lecture Charts. (London: Sampson Low, Marston, and Co., 1895.)

THIS is a series of diagrams intended to illustrate various chemical and metallurgical processes and apparatus, and designed more especially for the use of teachers who are preparing students for the examinations of the Science and Art Department, the London Matriculation, Oxford and Cambridge Local, &c.

There is no doubt that a good set of useful diagrams, of convenient size and moderate price, would be gladly welcomed by a large number of teachers, but the charts before us can scarcely be said to fulfil all the requirements of such a set of diagrams. The size of the sheets, namely, 30 in. × 40 in., is sufficiently large for the use of such classes as they are intended for, and it does not render them too bulky for convenient storage. In most cases the illustrations are very roughly executed enlargements of familiar cuts from various text-books and treatises on chemistry, sometimes well chosen, sometimes not. Many of the sheets contain several pictures, and where it happens that the subjects represented are in a manner related, this does not detract from their merit, except in so far as it necessitates the illustrations being smaller than if each occupied a single sheet. But in a number of instances the subjects depicted on the same diagram have no connection; thus, on the same sheet we find a representation of Hofmann's apparatus for showing the volume composition of water, and illustrations of certain apparatus used by Dewar in making experiments at low temperature.

Again, another diagram contains the following illustrations: (1) Hofmann's apparatus for composition of sulphur dioxide; (2) ozone apparatus; (3) apparatus for composition of ammonia; (4) apparatus for composition of hydrochloric acid; (5) Andrews' and Tait's ozone tube; (6) apparatus for composition of nitrous oxide; (7) Smithell's flame cone separator. With so many illustrations on one sheet, 30 in. × 40 in., each one must be almost insignificantly small, and quite erroneous ideas of the relative sizes of various pieces of apparatus are likely to be conveyed to the student. With some of the figures still more serious exception must be taken; thus, Fig. 2, Sheet 14, depicts a piece of apparatus, the design of which is of more than questionable feasibility; while Fig. 2, Sheet 17, is an impossible arrangement.

Many of the metallurgical figures are badly chosen. Thus, the old method for extracting zinc, known as "distillation per descensum," which has been quite obsolete for many years, is brought to life again in Diagram No. 11.

If these diagrams were a little better executed, and could be purchased singly, they would be of much more service to the general run of teachers, who could then select from a catalogue such as they might require.

G. S. N.

Brasilische Pilzblumen. Von Alfred Möller. Mit 8 Tafeln. (Jena: Gustav Fischer, 1895.)

THIS volume forms the seventh part of the "Botanische Mittheilungen aus den Tropen," edited by Prof. Schimper, of Bonn. The title—"Fungus-Flowers"—is suggestive of a popular and æsthetic treatment of the subject, but this impression is somewhat misleading, for Dr. Möller's work is of a strictly scientific character, and appeals more especially to systematic mycologists. At the same time, the extraordinary forms of the Fungi described give a considerable degree of general interest to the book, which is enhanced by the pleasant style in which the subject is treated. Dr. Möller is already well known for his mycological investigations, particularly for his fascinating work on the cultivation of Fungi by South American ants. The "Fungus-Flowers" are simply gastromycetous fungi of the family Phalloideæ, of which that repulsive plant the "Stinkhorn" (*Ithyphallus impudicus*) is the best-known British representative.

The author has been most fortunate in his investigation of the remarkable Brazilian forms of this family, which includes perhaps the most highly differentiated of the Fungi. He has founded no less that four new genera on his discoveries. One of these (*Protubera*) is referred to the Hymenogastreæ, and is of special interest, for it appears to connect that family with *Clathrus* among the Phalloideæ. The other new genera (*Blumenavia*, *Aporophallus*, and *Itajahya*) are members of the Phalloideæ, *Blumenavia* showing affinity with *Clathrus*, while the remaining two belong to the tribe Phalleæ. Eight new species are described in all.

The book is full of interesting details of the occurrence and mode of growth of these Fungi. It is illustrated by eight fine plates, many of the figures in which are from photographs of the specimens, while others represent their more minute structure. The first plate, a coloured representation of "the most remarkable of all Fungi," *Dictyophora phalloidea*, is especially striking. This is not one of the new species, but has never been adequately figured before. This extraordinary fungus bears a general resemblance to *Ithyphallus*, but is distinguished by the presence of an immense net-like indusium surrounding the stem, from which it stands out like a crinoline. The German colonists at Blumenau have given it the name of "the veiled lady."

Dr. Möller's book will be indispensable to students of mycology, and will no doubt attract more general attention to a most interesting group of plants, about which much still remains to be discovered. D. H. S.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The University of London.

SIR JOHN LUBBOCK does not seem to me to appreciate in the smallest degree the facts of the position.

His proposal is, as I and others understand it, that the result of the labours of the Statutory Commission "should be submitted to Convocation for their approval, *to be signified as at a material election.*"

The words which I have placed in italics propose a new procedure which I presume would have to be provided for in the Act. This is what for the sake of brevity has been called the *referendum.*

For reasons which I have sufficiently set out in my former letter I think the institution of the *referendum* extremely undesirable under any circumstances, and peculiarly open to objection in the present instance.

But I think we are now entitled to ask Sir John explicitly what he means when he says "it is the law at present," and that his "constituents highly value this right." In so grave a matter it is difficult to believe that he is indulging in a mere logomachy, or that he means seriously that the veto exercised under existing conditions and the new *referendum* are one and the same thing.

The meaning of the whole business is, of course, very simple. Convocation, in common with the Senate and practically everybody interested in the higher education in London, has expressed its approval of the Report of the late Commission as affording a basis for the reorganisation of the University. As Convocation is not to be moved from its decision expressed in the customary and constitutional way, the leaders of the minority, mainly drawn from the Faculty of Laws, have induced Sir John Lubbock to suggest a fundamental change in our procedure. The hope, of course, is that by this means a different result may be manipulated. I say "manipulated" because I entirely agree with Mr. A. W. Bennett, who in his admirable letter clearly indicates the kind of tactics we may expect. As the avowed object of the whole scheme is to set aside and nullify the action which Convocation has taken, I do not think that the language in which I described it is in any way inappropriate.

Sir John may be as polite as he likes to our intelligence. But what he has done is to constitute himself the instrument of those who would destroy the prospects of academic study in London, instead of making the University of London a better mechanism for the purpose for which it exists. And this is not what we had a right to expect of Sir John Lubbock.

Kew, August 10. W. T. THISELTON-DYER.

Note on Quaternions.

ON reading Cayley's famous memoir on matrices,[1] I have noticed in passing that in McAuley's[2] notation we may write in general,

$$\left.\begin{aligned} &\phi^{-1} = \underset{\phi}{D}\log m, & &\phi'^{-1} = \underset{\phi}{D}\log m\,; \\ &\psi = \underset{\phi}{D}m, & &\psi' = \underset{\phi}{D}m\,; \\ &\phi\underset{\phi}{D}\log m = \phi'\underset{\phi}{D}\log m = \psi^{-1}\underset{\phi}{D}m = \psi'^{-1}\underset{\phi}{D}m = 1. & & \end{aligned}\right\}\ldots\text{(A)}$$

where m is an invariant of ϕ, which being the original linear vector function, ψ is Hamiltonian inverse function, and I is the identity [illegible]; they are respectively defined by

$$mS\lambda\mu\nu = S\phi\lambda\phi\mu\phi\nu = S\phi'\lambda\phi'\mu\phi'\nu,$$
$$\psi = m\phi'^{-1}, \qquad I\rho = \rho.$$

I [illegible] we may prove the above relation by the variation formula

$$\delta Q = -Q_1S\delta\phi\zeta\underset{\phi}{D}_1\zeta,$$

given by Mr. McAuley, thus

[1] [illegible]

[2] [illegible]

$$\begin{aligned}\delta m &= -m_1S\delta\phi\zeta\underset{\phi}{D}_1\zeta = -S\delta\phi\zeta\underset{\phi}{D}m\zeta = -S\delta\phi\zeta\psi'\zeta \\ &= -S\delta\phi i\psi' i - S\delta\phi j\psi' j - S\delta\phi\kappa\psi'\kappa \\ &= -S\delta\phi i\phi j\phi\kappa - S\delta\phi j\phi\kappa\phi i - S\delta\phi\kappa\phi i\phi j \\ &= -\delta S\phi i\phi j\phi\kappa = \delta m.\end{aligned}$$

If W be any scalar function of ϕ, and if its independent variable be m (as it is so in some cases of the problems in elasticity, where m is the volume-dilatation), we might dispense with the notation $\underset{\phi}{D}$, for we may write in general,

$$\underset{\phi}{D}W = \frac{dW}{dm}\psi' \quad . \; . \; . \; . \; . \; . \; . \; . \; . \quad \text{(B)}$$

Also, if Q be any quaternion function of ϕ, and if its independent variable be m, we have again

$$\delta Q = -\frac{dQ}{dm}S\delta\phi\zeta\psi'\zeta \quad . \; . \; . \; . \; . \; . \; . \quad \text{(C)}$$

For, beginning with McAuley's form, we have

$$\begin{aligned}\delta Q &= -Q_1S\delta\phi\zeta\underset{\phi}{D}_1\zeta = -\frac{dQ}{dm}S\delta\phi\zeta\psi'\zeta \\ &= -\frac{dQ}{dm}[S\delta\phi i\psi' i + S\delta\phi j\psi' j + S\delta\phi\kappa\psi'\kappa] \\ &= \frac{dQ}{dm}\delta m = \delta Q.\end{aligned}$$

Japanese Legation, The Hague, July 16.

To Find the Focal Length of a Convex Mirror.

THE following method is so much simpler than those ordinarily used, that it may be of interest to your readers.

Use as object an opaque screen with a hole and pin-point, and painted white, or covered with white paper.

Set up on the bench in line, say, with the left edge of the hole, the convex mirror and an auxiliary biconvex lens of short focal length (six inches or so), and adjust the lens so that the image of the hole and pin-point is formed side by side with the object. The centre of the mirror is now at the point at which the image would be formed by the lens alone; this position may either be calculated or found (after noting the position of the mirror and then removing it) by means of a screen. Thus the radius is easily measured.

If the focal length of the mirror be greater than f that of the lens, the simplest way of adjusting is to put the lens as close as possible to the mirror, put the object at principal focus of lens, and move the object back until the image is formed as above.

If, however, the focal length be less, we can be sure of finding the position by putting the mirror at a distance of $4f$ from the object, and the lens at $2f$, and moving the lens back until the desired position is reached.

The following is a simple way of making a direct measure of the focal length of a concave lens:—

Use an object like the one mentioned above, an auxiliary convex lens (say six inches focal length) to produce a convergent beam, and an auxiliary plane mirror, placed beyond the concave lens.

Adjust until the image is formed side by side with the object as before, then the rays must be emerging parallel to one another from the concave lens, and hence the convergent beam from the convex lens will (when the concave lens and mirror are removed) form an image at the principal focus of the concave lens. A direct measure can thus be made of the focal length.

I may add that both methods are very simple in practice.

Grammar School, Macclesfield. EDWIN BUDDEN.

Oceanic Islands.

IT is to be hoped that in the programme of the present Government a place will be found for an item humble and unimportant in the politician's eyes, but to the biologist of the utmost urgency—the sending out of a scientific expedition or expeditions to study the fauna and flora of oceanic islands before they are exterminated by continental importations. Let it be granted that men of science are busy with problems of even greater interest than those which such expeditions might help to solve. But among all the ambitious aims of science, it would be hard to find one to which delay would be more ruinous than to this—the

thorough knowledge of the inhabitants, whether animal or vegetable, of oceanic islands. The work must be done speedily, or it will be too late: and it is work that can hardly be undertaken on a sufficiently extensive scale without aid from Government.

Haileybury College. F. W. HEADLEY.

MICROGRAPHIC ANALYSIS.

METALLURGISTS would have been greatly astonished if they had been urged at the beginning of the present century to gather information as to the composition of samples of iron and steel by merely looking at polished and etched specimens through a microscope. The operation is, nevertheless, rapidly taking its place in the ordinary routine of a works laboratory.

As regards the history of the development of this new branch of investigation, it appears that micro-metallography has not been developed from petrography. It is the natural extension of the study of meteoric iron, and, as has often happened in the history of science, it seems to have had more than one independent origin. Priority of date rests with our own countryman Dr. Sorby. In 1864 he submitted to the British Association photographs of opaque sections of various kinds of iron and steel, and he endeavoured to develop a method for the industrial examination of such sections under high powers, preferring polished sections to fractured surfaces. The abstract of his paper is very brief; but looking back, it seems strangely comprehensive and suggestive. He claimed that the sections showed "various mixtures of iron, two or three well-defined compounds of iron and carbon, of graphite, and of slag; and these, being present in different proportions, and arranged in various manners, give rise to a large number of varieties of iron and steel differing by well-marked and very striking peculiarities of structure."

Later, Prof. Martens, in Berlin, without neglecting the examination of sections, carefully studied, in 1878, the general laws which govern the occurrence and formation of fractures, fissures, blow-holes, and crystalline structure in metals and alloys. His work, therefore, presents all the characteristics of perfect originality. It was not long after the publication of Martens' work that M. Osmond, then engineer at the Creusot Works, began, with his colleague M. Werth, investigations on the cellular structure of cast steel. This work was published by the *Académie des Sciences* in 1885, and in order to trace the progress which has been made in micro-metallography during the past ten years, it would be difficult to do better than consult the beautiful monograph by M. Osmond which has recently been published by the *Société d'Encouragement* of Paris.[1]

As M. Osmond justly observes, metallography should in its early days be descriptive; it should enable us to determine the form and nature of the various constituents of alloys, to ascertain their mode of distribution, and to measure their dimensions. Later on, when sufficient data have been established, it will be possible to apportion the observed facts to their respective causes (1) by ascertaining the way in which the structure of a given metal changes under the influence of the three combined factors—temperature, time, and pressure, and (2) it will be possible to trace the relations between the observed facts and their consequences by defining the mechanical properties which correspond to a particular structure.

The first step in the complicated procedure is to cut and polish the opaque specimens of steel. The methods do not admit of condensed description, and the original memoir must be consulted, as even the technical manuals of crafts, in which the polishing of metals plays a part, give but little information that is useful in the preparation of metallic sections for the microscope. It must, however, be added that one method of polishing is specially designed with a view to wear away the softer constituents of the specimen, and bring the harder into relief. It is often useful to attack a polished specimen of steel with a reagent which will colour certain constituents only. For this purpose M. Guillemin treats sections of bronze by oxidation, at regulated temperatures, which produces varied colourations on several constituents of the alloy, while M. G. Charpy prefers an electrolytic attack. It is somewhat surprising to find that an infusion of *coco* (a popular French term for an infusion of liquorice) is very useful for the purpose, which recalls the fact that Japanese artificers have, for centuries, used plum-juice vinegar, decoctions of finely-ground beans (*Glycine hispida*), or extracts of the roots of certain plants, as valuable agents for colouring the peculiar alloys which they employ in art metal-work. It may be that the micro-metallographer has much to learn from the Japanese.

The "attack" of polished specimens is made by suitable reagents, which may be divided into the three classes—acids, halogens, and salts. Of the acids, nitric acid of 36° Baumé appears to be the most useful. Of the halogens the pharmaceutical tincture of iodine gives excellent results, as it removes carbon from the steel, and colours certain portions of the specimen. Such treatment, the nature of which has been so briefly sketched, will serve to reveal the main constituents of steel. These are five in number, and it has been found convenient to give mineralogical names to them, following the suggestion of the distinguished American metallurigist, Mr. Howe. Thus pure iron is called *ferrite*; the carbide of iron, Fe_3C, of Abel, *cementite*. This is not coloured by the infusion of *coco* or tincture of iodine, which latter leaves it of a silver-white brilliancy under vertical illumination. Dilute nitric acid in the cold does not affect *cementite*. The third material is one of the components of the "pearly constituent of Sorby," which may be coloured by coco or by iodine, and M. Osmond proposes the name of *sorbite* for it, though he is uncertain as to its exact constitution. The fourth constituent, to which he gives the name of *martensite*, is that which is ordinarily obtained by the rapid cooling of a specimen of steel during the familiar operation known as "hardening." It is a crystalline, fibrous substance which iodine colours readily either yellow, brown or black, according to the amount of carbon it contains. Now, martensite preserves its characteristic forms equally well in very low carbon-steels which have been hardened, as well as in high carbon-steels which have been subjected to this process. It may be urged, therefore, that martensite is not a carbon-iron compound which has liquated out of the mass, but that it represents the crystalline organisation, formed under the influence of carbon by one of the allotropic forms of iron.

The last of the five constituents of steel, marks the transition of soft iron into hardened steel. The name of *troostite* is after the eminent chemist, and it resembles sorbite, but its composition is as yet uncertain. This name is not well chosen, as a variety of silicate of zinc has long been known as troostite.

It will be evident that a micro-section of a mass of steel closely resembles a rock-section which has constituent minerals distributed through it. It should, however, be pointed out that there are cases in which the existence of these several constituents cannot be sharply defined, as it is frequently necessary to deal with transition forms which defy classification. Sorbite, troostite, and martensite appear to be solidified solutions of various forms of carbon in diverse forms of iron, for it seems clear that metallographic work on steel brings into prominence the existence of allotropic forms of iron.

In order to realise how complicated the structure of

[1] "Methode generale pour l'Analyse micrographique des aciers au carbone," par M. F. Osmond (*Bull. de la Soc. d'Encouragement*, vol. x., p. 4[illegible], 1895).

ordinary steel really is, reference must be made to some facts recorded in Nature, vol. xli. 1889, p. 32. An attempt was therein made to show that notwithstanding the importance of the part played by carbon in the hardening of steel, the phenomena of hardening cannot be explained solely by a change in the relations of carbon to iron. The iron itself appears to change its state, and M. Osmond has shown that it probably assumes at least three distinct allotropic forms, which he designates respectively as α, β, and γ iron.

The fact that the iron itself may exist in more than one state, brings into prominence the causes which underlie the difference between an ordinary rock-section and that of a metal or metallic alloy. In granite, for instance, as the fused mass cools the quartz, mica and feldspar fall out of solution in distinct crystalline masses; and although the fusibility of the mass, and consequently its structure, may be greatly influenced by the presence or absence of a small quantity of impurity, say two or three per cent. of sodium, still, so far as we know, complications do not arise from allotropy of the constituent elements of the rock. In the case of a specimen of carburised iron the conditions are widely different. It is certain that one very vital change in the relations between the carbon and the iron does actually take place at 650° C., that is to say, at a temperature far below the fusing point of the mass. The decomposition of the carbide of iron, Fe_3C, may take place at various rates. Cementite can, for example, under sufficient pressure, resist decomposition at a temperature well above that at which it would ordinarily decompose, and we are confronted with the complications which ensue when carbon is united, not merely with α iron, but with β or γ iron, so as to form either $Fe\beta C$ or $Fe\gamma C$.

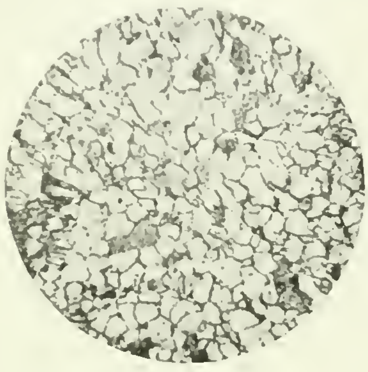

Fig. 1.

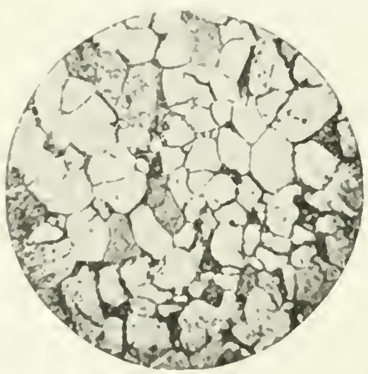

Fig. 2.

A few examples will serve to make the method of investigation clear. The effect of annealing steel is very remarkable. The operation consists in raising the metal to a high temperature and in allowing it to cool slowly. A granular structure is thus developed in the metal, the size of the polyhedral grains being proportional to the temperature to which the metal is raised. If the temperature is over 1000° C. the grains of ferrite (iron) will be large, while the perlite remains outside the grains and arranges itself in the joints round them. Fig. 1 represents a sample of very mild steel containing 0·14 per cent. of carbon which had been forged and etched with dilute nitric acid; while Fig. 2 represents the same steel which has been cooled from an initial temperature of 1015° C. In it the ferrite has arranged itself in larger grains than was the case in the first section, which had not been raised to nearly so high a temperature before cooling. Now compare this with Fig. 3, which shows the effect of raising the steel to an initial temperature of 960° C., allowing it to cool down to a temperature of 770° C., and then cooling it rapidly by quenching it in water. Microscopic examination shows that the interstitial matter is martensite, together with some troostite, while the principal mass is still ferrite in grains. These three specimens, chosen, it should be remarked, from the eighty-five beautiful photographs given by M. Osmond, serve to show how much the structure of the same variety of steel will vary with the thermal treatment to which the metal has been subjected. Fig. 4 shows a sample of more highly carburised steel polished with rouge, which presents a vermicular surface of ferrite and perlite.

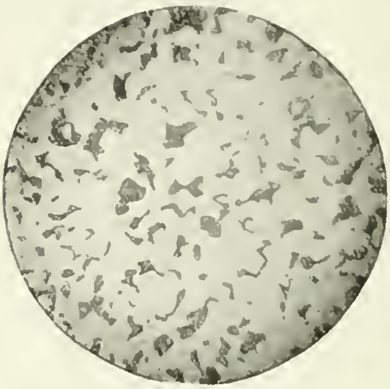

Fig. 3

Fig. 4.

There would appear to be no limit to the applications of micrographic analysis, as all metals and all alloys may be subjected to its action. It is known, for instance, that the qualities of the copper alloys are greatly modified by the addition of minute quantities of deoxidising agents, such as phosphorus, aluminium, or silicon, and

M. Guillemin, in an admirable paper on the metallography of the alloys of copper presented to the French "Commission des Méthodes d'essai des Matériaux de Construction,"[1] has given evidence that it is possible to pronounce with certainty, by the examination of etched surfaces of examples of the alloys, which deoxidiser has been employed.

It remains to be seen in what way the mechanical properties of steel are connected with the structural changes revealed by micrographic examination. In every specimen of steel, as has already been stated, at least three great molecular changes are produced as the metal is raised from the ordinary temperature to a white heat. The belief that the rearrangement of atoms in the molecule of iron (which is, in fact, allotropy) is really fundamental to these molecular changes, is rapidly gaining adherents, but authorities on hardening of steel are by no means in accord as to the true significance of allotropy in relation to that important industrial operation. The writer of this paper has long declared himself to be a pronounced allotropist, and many patient experimenters are hard at work at the problem. M. Charpy,[2] for instance, had already pointed to the peculiar behaviour of steel under longitudinal stress, as proof that the metal undergoes allotropic change. He now seeks, by an elaborate series of experiments, to ascertain whether the mechanical tests of steel which has been quenched at definite temperatures, support Osmond's view as to the significance of the part played by allotropy of iron in the hardening of steel. Charpy's opinion seems to be that, on the whole, his experiments do not afford conclusive evidence in support of Osmond's view. It may, however, be urged that in the case of steel, mechanical tests could not be expected to afford decisive evidence in relation to the theoretical significance of allotropy, because, as M. Osmond's micrographic work shows, the structure of steel is so complex and varies so much with thermal treatment. It is, of course, ultimate structure which determines the strength and elasticity of steel, and none of us claim that allotropy is the sole factor in the production of structure.

The magnetic behaviour of steel, on the other hand, as M. Curie has recently pointed out, is greatly influenced by temperature, for, within the range of 20° to 1350°, rapid variations in magnetic properties of soft iron reveal themselves at about 750°, 860°, and 1280°. This, as he says, is favourable to the views of M. Osmond, because on independent evidence we are led to conclude that at temperatures near these points the metal undergoes allotropic modifications.

It is to be hoped that microscopic analysis will soon take its place in the ordinary routine of every steel works laboratory, and it should be added that in this country two well-known authorities, Mr. T. Andrews and Mr. J. E. Stead, constantly employ it, while Mr. A. Sauveur[3] has originated the system already in the works of the Illinois Steel Company. W. C. ROBERTS-AUSTEN.

THE SCIENTIFIC RESULTS OF THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE annual meeting of the British Medical Association is, no doubt, increasing in importance, since it is becoming a congress for the demonstration of the advance of medicine. The work of the meeting may be considered as belonging to two classes, the practical and the scientific. Many, no doubt, who attend the annual meeting, do so with the object of gaining practical help in both the medical and the surgical treatment of their patients; and this help the annual meeting gives in abundance. One of the most important parts of the meeting, however, is that which is occupied with the progress of scientific medicine, and consists not so much in the announcement of startling discoveries (for with these medicine has but little to do), but in the revision and criticism of the facts discovered by experiment and at the bedside.

Medical science is becoming more exact, as the knowledge of the functions of living tissues (physiology) and their changes in disease (pathology) increases.

It is not so many years ago when the chief subject in what was called physiology was histology, or the structure of the tissues. Physiology proper then rapidly progressed, and although at first it was considered from a somewhat too physical standpoint, and indeed is still so considered by some, yet it has received an enormous impetus by being associated with the study of chemistry and of the action of the chemical constituents of the body on the living tissues. This is evidenced in the excellent address on "Internal Secretion," given by Prof. E. A. Schäfer, F.R.S., of University College, a subject which in its scientific aspects is of a quite recent development. A secretory organ may, like the stomach, salivary glands, &c., separate materials from the blood and pour them into a cavity, in which they are utilised; this may be called external secretion. On the other hand, "some secreted materials are not poured out upon an external surface at all, but are returned to the blood"; these may be called internal secretions. Although it is probable that in the widest sense every tissue has an internal secretion, yet this is most obvious in the ductless glands, such as the thyroid, the suprarenal bodies, and the pituitary body. But in one gland with an important external secretion, viz. the pancreas, there is also an internal secretion which is of great value in the economy.

The subject of internal secretion has developed hand in hand with clinical medicine, and it was the observation of patients which first, as in the case of the thyroid, gave the clue to the line of investigation. It is impossible in this place to give a detailed account of Prof. Schäfer's address; it is well worthy of study by every one interested in the progress of biological science. It will not be out of place, however, to illustrate the subject of internal secretion by quoting as examples the investigation of the pancreas and the suprarenal capsules, the latter of which has been the subject of special study by Prof. Schäfer, in conjunction with Dr. G. Oliver and Mr. Moore.

The association of disease of the pancreas with the presence of sugar in the urine has long been noted; although only a certain proportion of cases of diabetes show any great changes in this organ. If the pancreatic juice be diverted from the intestine, or if the duct be blocked, the animal experimented upon does not die, there is no glycosuria, nor does it apparently suffer any great nutritional change. If, however, the pancreas be totally extirpated, glycosuria appears, and the animal invariably dies; this does not occur, however, if only a part of the organ be removed. More than this, if a portion of living pancreas be successfully grafted into an animal from which the organ is subsequently completely removed, no evil results follow. Besides its obvious and important function of secreting a digestive juice, the pancreas therefore produces some material which it gives to the blood, and which is essential for the continuance of life: this is the internal secretion. On the other hand, it is suggested that the organ nominally separates and transforms some toxic substance which is fatal to existence; this is the theory of auto-intoxication. The internal secretion of the suprarenal capsule is more obvious, perhaps, than that of the pancreas. The capsule is a ductless gland: it has no external secretion. The complete

[1] "Analyse Micrographique des Alliages." (*Comptes rendus*, vol. cxv. p. 232, July 25, 1892.)
[2] "Bull. de la Soc. d'Encouragement," vol. x. 1895, p. 660.
[3] "Trans. Amer. Soc. Mining Engineers," vol. xxii. p. 546.

removal of both suprarenal capsules results in rapid death, which is preceded by great muscular weakness, diminished tone of the vascular system, and some nervous symptoms; a combination of events which is seen in Addison's disease, which is a disease of these organs. From the medullary portion of the gland, Schafer has obtained an extract containing an active substance which is remarkable as producing its effects in very small doses (as little as $5\frac{1}{2}$ milligrams in a dog weighing 10 kilos.), and as being capable of withstanding for some time the temperature of boiling water. This substance increases the duration of the contraction of muscle, as tested by the apparatus ordinarily in use in the physiological laboratory; but it has a more remarkable effect in greatly increasing the blood pressure, a result following a direct action on the peripheral arteries. In the case of the suprarenal capsule, there is thus distinct evidence of internal secretion; that is, of the presence in one part of the gland of a substance which has a well-marked physiological effect. Into all the questions arising out of this subject it is impossible now to enter. The subject is one of vast importance to scientific practical medicine. As the results of future investigation, we may hope to obtain not only a greater knowledge of the pathology of some obscure nutritional diseases, but some indications for their relief and treatment. This has already been accomplished in the case of myxœdema, in which the thyroid gland is degenerated, and in which very great benefit is obtained by feeding the patients with fresh thyroid gland, or by injecting the extract.

One other scientific result of the annual meeting may be viewed. It is the predominant place now given in the study of disease to the question of infection. All disease is not infective, but infection, in theory, has for many decades played an important part in pathology. The great change which has come over medical science is, that the question of infection is now studied from an experimental point of view. Vague theories have given place to facts, which are of prime importance, not only in the understanding of disease, but in its treatment. In the investigation of diseased, as well as of normal functions, the application of chemical methods has been of great service, and is destined to be of still greater importance.

The accurate study of infection deals with a far wider subject than the characteristics of the infective agent; since it is also concerned with the reaction of the body against the micro-organism and the poisonous chemical substances this produces. The study of this reaction of body has, from the morphological point of view, given a clearer view of the processes occurring in inflammation; and from the chemical point of view, it has opened up a wide field of possible therapeutical agents. The prospect is one which is reassuring for the future. The fact that infection is being so closely studied, and that the infective agents in so many diseases have been isolated, is of great importance to the human race; since infection is preventible. The fact that the body, in reacting against an infective disease, produces a substance which counteracts invasion, as well as the poisonous bodies formed by the infective agent, is of as great importance as the first point; since an infective disease may be cured. At the annual meeting, the discussion on pneumonia as an infective disease (a discussion which would have been impossible, and would even have been considered heterodox only a few years ago) as well as the discussion on the utility of the diphtheria anti-toxin, illustrates the point mentioned. In the discussion on diphtheria, the great majority of the speakers, both those who considered the subject from the scientific aspect and those who looked at it simply from the practical point of view, agreed that the use of the anti-toxin in the disease was not only based on a firm scientific basis, but that it had completely changed the aspect of the disease. Whatever the limitations of the treatment by anti-toxic serum may in the future be proved to be, there can be but little doubt that its discovery marks an epoch in the treatment of infective disease.

THE IPSWICH MEETING OF THE BRITISH ASSOCIATION.

THE arrangements for the meeting of the British Association at Ipswich this autumn are making rapid progress. The General Election somewhat interrupted the preparations of the local secretaries, but the excitement being now over, general attention in the locality is again centred on the coming visit of the Association, and great efforts are being made in the town and neighbourhood to ensure the success of the meeting. The chief public buildings in the town are just emerging from the hands of the painter and decorator. The reception room will be located in the Town Hall, the council chamber being the room actually set apart for the purpose, whilst the library will be the writing room. The President's address and the evening discourses will be delivered in the public hall, as will also the lecture to working men. In the matter of Section rooms, the Local Committee will be able to offer the Association very good accommodation, as there are fortunately a number of suitable rooms and halls in the town within a very short distance of each other, and all are close to the reception room. The two halls at the Girls' High School, which were formerly the New Assembly Rooms, and were used for the reception room and for Section E on the occasion of the Ipswich meeting in 1851, will be allotted to Section A (Mathematical and Physical Science) and Section B (Chemistry). About two hundred yards distant is the Co-operative Hall, in which Section G (Mechanical Science) will meet. Section C (Geology) will be accommodated in the Art Gallery adjoining the Museum. Section D (Zoology) and the new Section K (Botany) will have, respectively, the banquet room and the lodge room at the Masonic Hall. The Lecture Hall, adjoining the Ipswich Institute, will be given over to Section E (Geography), whilst across the street, the Working Men's College (formerly known as the Old Assembly Rooms) will be set apart for Section H (Anthropology).

The proceedings will commence on the evening of Wednesday, September 11, when the Marquis of Salisbury will retire from the presidential chair, and Sir Douglas Galton will take his place. The new President will then proceed to deliver his address. The second evening will, as usual, be devoted to a conversazione, which will probably be held in the museum and the adjoining buildings, used as art and technical schools. On Friday evening Prof. Silvanus P. Thompson will deliver a lecture on "Magnetism in Rotation." On Monday evening Prof. Percy F. Frankland will discourse on "the work of Pasteur and its various developments," and on Tuesday there will be a soirée given by the Ipswich Scientific Society and the Suffolk Institute of Archaeology jointly. This, like the first soirée, will probably be held in the Museum buildings. The lecture to working men will be given on the Saturday evening by Dr. Alfred H. Fison, who takes "Colour" for his subject.

In response to a special invitation which the Local Committee issued to foreign men of science, the following gentlemen have signified their intention of being present at the meeting:—Prof. A. Gobert (Brussels), Prof. W. E. Ritter (Heidelberg), Rev. T. Adams (Canada), M. J. Dantzenburg (Paris), Dr. O. Maas (Munich), M. Boule (Museum d'Histoire naturelle, Paris), Prof. Ira Remsen (Johns Hopkins University, U.S.A.), Prof. Runge (Hanover), Prof. E. C. Hansen (Copenhagen), Dr. van Rijckevorsel (Rotterdam), M. G. Dolfus (Paris), His Excellency Don Arturo de Marcoartu, M. E. van den Broeck

(Brussels), Prof. Michie Smith (Madras), M. A. P. N. Franchimont (Leiden), Dr. H. Haviland Field (New York), Dr. Bashford Dean (Colombia College, New York), Prof. J. W. Langley (Ohio, U.S.A.), Dr. Paschen (Hanover), Dr. Conwentz (Dantzic), M. Berthelin (Paris). A large number of the leading scientific men in England have already notified that they will attend the meeting.

The hon. local secretaries for the meeting are Messrs. S. A. Notcutt, G. H. Hewetson, and E. P. Ridley. All communications to them should be addressed to the Museum, Ipswich.

BAILLON, BABINGTON, EATON.

BY the death of Henri Ernest Baillon, France has lost one of her most accomplished botanists, and certainly her leading systematist. Under date of the 19th ult. the writer received the following lines from a friend at the Muséum d'Histoire naturelle, Paris.

"Je vous écris sous une bien pénible impression; M. Baillon est mort hier soir subitement. Dans l'après midi il était venu au laboratoire selon son habitude. À 5 heures et demie il prit un bain: à 6 heures son fils rentrant de l'École de Médecine le trouva mort. On croit que le bain, un peu trop chauffé, a déterminé une congestion.

"C'est une grande perte pour nous et pour la botanique. S'il avait des ennemis implacables, il avait aussi des amitiés fidèles. Je ne doute pas que l'avenir ne montre que derrière un esprit, dont les manifestations parfois acerbes visait moins la personnalité que ce qu'il jugeait être l'erreur, se cachait un cœur sensible a l'excès. Il est un bon nombre de ses élèves pauvres qui savent de quelles délicatesses il savait entourer une aumône.

"Quoiqu'il en soit c'était un grand botaniste; vous le jugez ainsi, n'est ce pas?

"Ses quatre enfants vont se trouver dans la misère la plus profonde qu'on puisse imaginer. Ce qu'il n'a pas dépensé de sa fortune pour la publication de ses livres a disparu dans le gouffre des dettes de celle qui a porté son nom. Aujourd'hui il ne reste rien."

The allusion to Baillon's personal character in the foregoing letter will appeal to the sympathies of those who knew him on this side of the channel. Unfortunately he quarrelled with some of the foremost French botanists of assured position, which led to regrettable and undignified recriminations on his part, and resulted in closing the doors of the Académie des Sciences against him for ever. This embittered his life considerably, and rendered his relations with a section of the botanists of Paris almost unbearable.

For most of the following particulars of Baillon's career I am indebted to the author of the above letter. Henri Baillon, as he usually signed himself, was born at Calais, November 29, 1827, of a family of good position and reputation in the town and district. He studied with great distinction at the Lycée de Versailles, and commenced his medical education at the age of seventeen. In 1854 he became house-surgeon at the Hôpital de la Pitié, Paris, a position obtained only by severe competition; and he was so brilliantly successful in his work, that he was unanimously awarded the gold medal of the Internat, the highest reward at the disposal of the Faculté de Médecine. His candidature for the degree of Docteur en Médecine was a perfect triumph, for he completely held his examiners, both by the elegance of his diction and the depth of his scientific views. In 1863 he succeeded Moquin Tandon in the Chair of Botany at the École de Médecine, and he filled this chair up to the time of his death; and for some time was Professor of Botany at the Lycée Napoléon as well. He was also Docteur ès Sciences. In 1875 he was elected a foreign member of the Linnean Society of London, and last year he received the same distinction from the Royal Society. This gave him much pleasure, and consoled him, in some measure, for the implacability of his own countrymen. In 1866 he and a few others founded the Société Linnéenne de Paris. He was elected president, and continued to act as such until his death. For some years the *Proceedings* of this very small Society were published in Baillon's own periodical, *Adansonia*, and then a *Bulletin Mensuel* appeared, and has continued to appear down to the present time, entirely owing to the energy and industry of the president. This organ was not published, but distributed to the leading botanical establishments; hence there is no record of Baillon's numerous articles therein in the Royal Society's catalogue of scientific papers. Yet, omitting these, the catalogue contains the titles of 230 of his papers, published between 1854 and 1883. But Baillon was a most prolific writer, and covered a considerable range, though systematic botany was his chief study. I need only name his *Adansonia*, twelve volumes, 1866 to 1879; "Dictionnaire de Botanique," four volumes, 1876 to 1892; "Histoire des Plantes," 1867–95, and still unfinished. Baillon, too, was the only French botanist who occupied himself on the rich collections of flowering plants in Paris from Madagascar; being the author of the uncompleted "Histoire des Plantes de Madagascar," forming a portion of Grandidier's great work on Madagascar.

Baillon was one of the few existing botanists having a good knowledge of the phanerogamic flora of the world. As a writer, however, he was more critical than methodical, and many of his original observations and suggestions have been overlooked by botanists who have subsequently gone over the same ground. This is owing to the fact that the titles of many of his articles do not sufficiently describe their contents. Not infrequently a new genus or a new species is described in the body of a paragraph, and sometimes so informally, that only by careful reading is it possible to arrive at the fact. This often caused the author himself chagrin, especially as he was very sensitive and apt to believe that his work had been purposely ignored. I had almost forgotten to mention that the Euphorbiaceæ were one of his favourite families, and his "Étude Générale du Groupe des Euphorbiacées" is one of his most finished works. This is not the place to enter into a more critical examination of his works, but I cannot help mentioning that the illustrations almost throughout are of a high order of merit. Dr. Baillon has been a frequent visitor to Kew and the British Museum during the last thirty years, and many botanists will join me in regret for his sudden death whilst apparently in almost the full vigour of life.

The veteran Professor of Botany, Charles Cardale Babington, in the University of Cambridge, whose death has lately taken place, was born at Ludlow in 1808, and educated at St. John's College, Cambridge, taking his B.A. in 1830 and M.A. in 1833. As long ago as June 1830, he was elected a Fellow of the Linnean Society; yet there are still two of earlier date in the Society's list, namely, Dickinson Webster Crompton and William Pamplin, both elected the previous January. There are only two others, Thomas Archer-Hind and James Bateman, who have been Fellows of the Society for upwards of sixty years. In 1851 Babington was elected a Fellow of the Royal Society, and among the fifteen of that year, it may be mentioned, were the late Prof. Huxley, Lord Kelvin, Sir James Paget, and Sir Gabriel Stokes. In 1861 he succeeded the Rev. J. S. Henslow in the Botanical Chair at Cambridge, a post he held up to his death, though for many years he was incapacitated from performing the duties. Prof. Babington was, in his early years at least, a prolific writer, his first paper appearing in 1832. His writings were almost exclusively on the British flora; and his name will stand in the history of British botany as the inaugurator of a more critical delimitation

of species than had previously found favour in this country. Taking Koch and Fries as his models, from whom he largely borrowed, he published the first edition of his "Manual" in 1843. This new departure caused considerable commotion and opposition from the older school of botanists; and the fact that Babington did not possess the critical acumen and originality of the masters in his adopted school, sometimes exposed him to attacks. Nevertheless the "Manual" was a success, passing through eight editions, the last of which appeared in 1881; and it still enjoys great favour, even among those who do not go so far in the matter of species. Babington was also author of several local floras; the first being the "Flora Bathoniensis," 1834; followed by the "Flora Sarniensis," 1839, and a "Flora of Cambridge," in 1860.

Daniel Cady Eaton, who belonged to a school of American botanists, of whom very few survive now, was the grandson of Amos Eaton, the author of the formerly famous "Manual of the Botany of North America," which passed through many editions; and son of General Amos E. Eaton, also a devotee of natural history. D. C. Eaton was born in 1834, and early evinced a liking for botany. After a successful career at school and college, he experienced many changes, including service in the federal army during the civil war. In 1867 he was called to the Botanical Chair of Yale College, New Haven, which he held until his death. As an author he will be best remembered by his writings on North American, Mexican, and West Indian ferns. His principal, or at least most popular, work is his "Ferns of North America," illustrated in colours by J. H. Emerton and C. E. Faxon.

W. B. H.

NOTES.

DR. BERGH, of Copenhagen, has been elected a Correspondant of the Paris Academy of Sciences, in the Section of Anatomy and Zoology.

THE resignation is reported of Mr. R. Trimen, F.R.S., Curator of the South African Museum, Cape Town, and also of Mr. R. L. J. Ellery, C.M.G., F.R.S., Director of the Observatory at Melbourne.

THE deaths are announced of Dr. Adolf Gerstacker, Professor of Zoology in the University of Greifswald; Dr. Pellegrino Strobel, Director of the Natural History Museum at Parma; Prof. H. Witmeur, Professor of Mineralogy and Geology in the University of Brussels; and Dr. W. Fabritius, Astronomer at the Kieff Observatory from 1876 to 1894.

THE French Association for the Advancement of Science met at Bordeaux last week. It was at Bordeaux that the Association held its first meeting in 1872, and this year the same cordial hospitality was accorded to its members as was given twenty-three years ago. The president of the recent meeting was M. Émile Trélat, and in his presidential address on "La Salubrité," he indicated the place of hygiene among the sciences, and traced its limits.

THE annual congress of the British Institute of Public Health was opened at Hull on Thursday last, under the presidency of the Mayor. On Friday, Sir A. Rollit delivered an address as president of the municipal and parliamentary section of the Institute, and Dr. Cameron delivered an address in the section of preventive medicine. It was resolved on Monday "That in the interest of public health all municipal and local authorities should be empowered to provide crematoria, and that a petition be presented to Parliament in support of the Bill about to be promoted to secure this object." Prof. W. R. Smith brought forward the subject of the influence of schools on diphtheria, and in the course of his remarks contended that schools did not play that important part in the spread of diphtheria which they had been supposed to do. The final sitting of the congress was held on Tuesday, when the reports of the several sections were adopted, and a resolution was passed that every house in a watering-place where lodgers were accommodated should undergo a survey by the sanitary authority, and that a certificate of fitness should be compulsory.

THE annual summer meeting of the Institution of Junior Engineers, the headquarters of which are in London, takes place from August 17 to 24, the rendezvous being Belgium. The towns to be visited include Antwerp, where the municipal docks, M. Kryn's diamond-cutting works, and other places of interest will be opened to members' inspection. At Ghent, MM. Carel's engine works, M. de Hemptinne's cotton-spinning works, and M. Van Houtte's nursery gardens will be seen; at Brussels, the electric lighting station; whilst at Liège, the works of the Société Cockerill, the Vielle Montagne zinc works, the St. Leonard locomotive works, the Val St. Lambert glass works, the Small Arms Factory, and the Electric Tramway Installation will be visited. In honour of the Institution a banquet is to be given by the Liège section of the Society of Engineers from the University, and the members will also be the guests of the Société Cockerill. An excursion to Verviers, where the Chamber of Commerce will entertain the visitors, is arranged for the purpose of seeing works in connection with the woollen cloth industry. Here MM. Peltzer's works and those of M. Duesberg-Delrez, La Vesdre, and M. Hauzeur Gerard fils, will be opened. The celebrated Gileppe reservoir, from which Verviers receives its domestic and manufacturing supply, is also included in the programme. A large number of members have notified their intention of being present at the meeting, which promises to be one of the most successful the Institution has held.

AN auto-mobile carriage race between Chicago and Milwaukee, promoted by the *Times-Herald* of Chicago, will be decided on Saturday, November 2, the object being to encourage and stimulate the invention, development, perfection, and general adoption of motor carriages. The amount offered in prizes is 5000 dollars, apportioned as follows: First prize, 2000 dollars and a gold medal, open to competition to the world; second prize, 1500 dollars, with a stipulation that, in the event the first prize is awarded to a vehicle of foreign invention or manufacture, this prize shall go to the most successful American competitor; third prize, 1000 dollars; fourth prize, 500 dollars. The third and fourth prizes are open to all competitors, foreign and American. The rules laid down stipulate, among other things, that no vehicle shall be admitted to competition which depends in any way upon muscular exertion, except for purposes of guidance. Competing vehicles which derive their power from petroleum, gasoline, electricity, or steam, and which are provided with receptacles for storing or holding the same, will be permitted to replenish the same at Waukegan, Ill., and at Kenosha, Wis., but at no other points.

DURING the past week the weather over the United Kingdom has been very unsettled, owing to the advance of various low-pressure areas from the Atlantic. Several heavy thunderstorms have occurred, the most severe being on Saturday night, the 10th inst., over the southern and south eastern parts of England. In London the storm was very violent, and the lightning was of unusual brilliancy. The disturbance travelled from south to north, and was accompanied by heavy rain. An exceptionally heavy thunderstorm also occurred at Holyhead on the same night, and the rain measured there on the next morning amounted to 2·08 inches. The *Weekly Weather Report* of the 10th inst. states that the rainfall for the week exceeded the average in all districts, the amount over England being about twice as much as the mean.

The Meteorological Office has received through the Colonial Office a report from the Governor of Hongkong, according to which it appears that the colony was recently suffering from a great drought; the rainfall from January 1 to June 23 last having been only 13·7 inches, being a deficit of no less than 28·7 inches on the mean of the corresponding period of the previous five years. The Governor draws attention to the fact that between October 1893 and April 1894, the colony suffered much from want of rain, and that the plague of the latter year was supposed to have originated from a deficient water supply. Though the drought of the first half of this year has been far more serious than that of 1893–94, the plague has not yet re-appeared in an epidemic form; but the reservoirs had, at the date of the despatch (June 26), only about a week's supply left in them. From a return furnished by the Director of the Hongkong Observatory, it appears that the greatest deficiency has occurred during May and June, when it amounted to 11 and 12½ inches respectively.

La Technologie Sanitaire is the title of a new journal devoted to questions of water supply and applied hygiene. It is published in Louvain, and is edited by a civil engineer, Victor J. Van Lint. The first number, amongst other contributions, contains an interesting and useful article by M. Ad. Kemna, the well-known Director of the Antwerp Waterworks, on "The Theory of Sand Filtration." The practical genius of the English in the past is emphasised in commenting upon Simpson's introduction of sand filters in London in the year 1839, and we are told that having produced such brilliant results, it is not surprising that as a nation we are so slow and reluctant to adopt more modern methods and change our system of technical instruction! Besides original articles, reviews of books are also appended, and what, perhaps, is one of the most useful features of this undertaking, is the bi-monthly issue of a supplement, international in character, containing a bibliography of books, pamphlets, &c., published on subjects connected with water supply, together with short notices of public hygienic enterprise in different parts of the world.

Infra-red light is invisible to us either because the humours composing the eye are opaque to it, or because the light is incapable of exciting the retina. Cima and Janssen have adopted the former explanation, but the alternative one has been accepted by Tyndall, Engelmann, and others, while Helmholtz maintained that the strong absorption suffered by infra-red rays in their passage through the eye is sufficient to account for their invisibility. That they are strongly absorbed has been found by all observers, but Herr E. Aschkinass proves, in the last number of *Wiedemann's Annalen*, that there is no sudden increase of absorption beyond the red end of the spectrum, and that the absorptive powers of the various media of the eye are practically the same as that of water. The apparatus used for this investigation contained a fluor-spar prism and a bolometer. Thin layers of the humours of an ox eye and a human eye were interposed in the path of the rays from a zircon burner, and the absorptive effects noted by means of the bolometer. It was found that at a wave-length of 0·81 μ, the limit of the visible spectrum, the absorption was 5 per cent. for the whole human eye. This increased to 10·5 per cent. at 0·872, reached 60 per cent at 0·98, decreased to 34·5 per cent. at 1·095, and finally reached 100 per cent., or total absorption, at 1·4 μ. This shows that a large proportion of infra-red light does reach the retina through the eye, but is not capable of affecting the nerves and producing visual sensation.

The last number of the *Wissenschaftliche Beihefte zum Deutschen Kolonialblatte* (Bd. viii. Ht. 2) is a further illustration of the care with which the German Colonial Society is organising the scientific investigation of German Africa. The present number contains the calculations by Dr. Fritz Cohen, Dr. L. Ambronn, and Dr. W. Brix, of the astronomical observations made by Dr. Grüner in Togo-land, and by Ramsay and Stuhlmann in German East Africa. There are also valuable tables of meteorological observations, made in German South-West Africa, and in Kondeland, and from the Marshall Islands; from the last locality comes an especially useful table showing the diurnal variation in atmospheric pressure, and giving the mean reading for every hour for each month in the year. Preuss contributesa report on the geography of the Smaller Cameroons, and Steinberg one on the diseases of the natives of the Marshall Islands. There is also a detailed study, by Dr. O. Warburg, of a beetle (*Herpetophygas fasciatus*) parasitic on the coffee trees in German East Africa. A good plate shows the insect in its various stages, and also illustrates its ravages on the trees.

Herr Oscar Neumann has published a preliminary account of his recent important expedition across Masai-land to Uganda in the last number of the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin* (Bd. xxii. No 4–5). Herr Neumann went out to East Africa in November, 1892, and after spending some months in preparation there, left for the interior on April 27, 1893. The caravan, consisting of 135 men, started from Tanga, and passing the southern border of the Usambara country, crossed Nguru to Irangi. Here a series of accidents, exhaustion of supplies, and some severe fighting with the natives, during which Herr Neumann was wounded in the mouth by an arrow, compelled the expedition to retreat southward to Mpwapwa. After resting there the party went northward across Irangi to the Gurui Mountain. This was ascended, though with considerable difficulty. Upon the higher slopes an interesting series of Alpine plants were found, including Azalea and Rhododendron. No trace of a crater remains near the summit, but some small craters occur in an adjoining valley. From Gurui the expedition followed up the East African Rift Valley, along Baumann's route past the salt lakes of Manyara and Natron. He examined the volcanoes Doenyo Kavinjiro and D. Ngai; on the latter he found a steam vent below the summit. From this point he followed Fischer's track past Nguruman to the south-west of the volcano of Suswa. Thence he turned westward to the shore of the Victoria Nyanza in Kavirondo, where the expedition again had great difficulties with the natives. Marching round the Nyanza through Usoga, he reached Uganda, but the excessive caution of an English officer prevented his reaching Mt. Elgon. From Uganda, which he describes as unhealthy and poorer than Usoga, he returned along the English road, across Mau, and past Naivasha and Machakos to Kibwezi, whence he diverged to Taveta, and Kilima Njaro, and thus back to the coast at Mombasa, where he arrived on February 5, 1895. The zoological collections made are very extensive, including 600 species of birds, 90 species of reptiles and amphibia, 50 species of mollusca, and about 1000 species of insects, and 90 species of mammals, of which five have been described as new by Matschie.

Dr. Otto Kuntze has recently issued, under the title of "Geogenetische Beitrage" (Leipzig, 1895, 78 pp.), a series of papers dealing with various geological problems, on which his journeys have thrown light. The first paper gives the evidence for some oscillations of level in the Andes, based on the inclination of some beds of iron-stained sands and laterite, and on the distribution of plants. He states the evidence with care, as it shows that the alterations of level have occurred quietly and without any sudden catastrophic changes. A second paper discusses the evidence on which it is claimed that there was a glaciation in Carboniferous times. The phenomena, often regarded as a proof of this, is attributed by Dr. Kuntze to wind erosion. He gives a figure showing perched blocks and

rounded rock surfaces in the Sierra de Tandil in the Argentine Republic, which have thus been formed. The third article in the series discusses the organic and chemical theories of the origin of the Chilian deposits of saltpetre. The next subject considered is the method of the silicification of fossil wood: the author readvances his old theory, and replies to the criticisms made by Rothpletz and Solms-Laubach upon it, and advances nine arguments against Solms-Laubach's rival theory. The fifth paper describes cases in which deposits of salt have been formed under continental instead of marine conditions, which the author explains as due to the decomposition of minerals containing chlorine in rocks destroyed by subaerial denudation. The last and longest paper in the collection, rediscusses the old problem of the formation of coal. He considers the three alternative theories as to whether coal is allochthon, *i.e.* formed from vegetable material deposited elsewhere than on its place of origin; or is autochthon, or formed by the decay of plants *in situ*; or is pelagochthon, *i.e.* formed under the sea. The author advocates the last. He gets over the difficulty of Stigmaria, by declaring that his fellow botanists are wrong, and that its supposed rootlets are really floating leaves. He says that the figures, given in the text-books, are all copied from one source, and declares that there are no specimens in the museums of "Dresden, Vienna, London, Paris, Berlin, &c.," which give any support to the rootlet theory. He gives an ideal view of a landscape in the Carboniferous period, showing the Stigmaria spreading over the floor of a sheet of water, with the "rootlets" rising as aquatic leaves.

MR. JAMES R. GREGORY, the mineralogist and dealer, wishes it to be known that he has removed from 88 Charlotte Street, Fitzroy Square, to more convenient premises at 1 Kelso Place, Kensington, W.

MESSRS. CHAPMAN AND HALL have been constituted sole agents in this country, the continent, and the colonies, for the sale of the important scientific and technological publications of Messrs. Wiley and Sons, of New York.

THE August *Journal* of the Anthropological Institute contains papers on Prehistoric remains in Cornwall; the northern settlements of the West Saxons; changes in the proportions of the human body during the period of growth; the languages spoken in Madagascar; and on a collection of crania of Esquimaux. There is also a description, by Mr. M. V. Portman, of the methods that should be employed by anthropological photographers.

WE have received a copy of a "Report on Slavery and the Slave Trade in Zanzibar, Pemba, and the Mainland of the British Protectorates of East Africa," by the Special Commissioner of the British and Foreign Anti Slavery Society. The Commissioner spent pretty nearly six weeks in East Africa in studying the subject. Probably the most valuable and trustworthy conclusion in this report, though perhaps not the one to which [illegible] attaches most importance, is that "the whole question of slavery in Zanzibar and Pemba is a very complicated question."

THE volume of *Transactions and Proceedings* of the New Zealand Institute for the year 1894, has reached us. A few of the papers have already been noted in these columns, and as more than seventy papers are included in the volume now [illegible], it is only possible for us to refer to a few of them. A [illegible] list of Coccids, reported from Australia and the [illegible] up to the end of last year, is given by Mr. W. M. Maskell. Sir W. L. Buller, K.C.M.G., F.R.S., has several [illegible] papers in the volume, and Captain F. W. Hutton, F.R.S., adds to our knowledge of the axial skeleton in the Dinornithidae, and there are a number of other papers referring to the same [illegible]. Prof. Arthur Dendy describes some land planarians, bringing the total number of species found in New Zealand up to twenty. The editor of the volume, Sir James Hector, K.C.M.G., F.R.S., contributes several papers to it, and the Rev. W. Colenso, F.R.S., with others, make contributions to the knowledge of the botany of New Zealand.

AMONG the new editions lately received is a translation of Prof. Oscar Hertwig's book "Die Zelle und Die Gewebe," published by Messrs. Swan Sonnenschein and Co. The work has been translated by M. Campbell, and edited by Dr. H. Johnstone Campbell. As we reviewed the original edition in 1893 (vol. xlvii. p. 314), it is only necessary to express satisfaction that such an important treatise on the functions and structure of cells has been brought within the reach of students who do not read German easily. Under this translation from the German, we find on our table two translations into German of papers by British men of science. The papers are published by W. Engelmann in Ostwald's *Klassiker der Exakten Wissenschaften*. No. 61 of this series contains George Green's essay on the mathematical analysis of the theories of electricity and magnetism, edited by Dr. A. J. von Oettingen and Prof. A. Wangerin, and No. 62 is a translation of papers on the physiology of plants, published by Thomas Andrew Knight between 1803 and 1812. This is edited by Prof. H. Ambronn. A third volume (No. 60), just received in the same series, contains papers by Jacob Steiner on geometrical construction, and is edited by Dr. Oettingen. In the Aide-mémoire Series, published by Gauthier-Villars, we have received two books on ballistic subjects, viz. "Balistique Extérieure," by M. E. Vallier, and "Bouches à Feu," by Lieut.-Colonel E. Hennebert. We have also before us "An Elementary Text-book of Mechanics," by Mr. W. Briggs, and Mr. G. H. Bryan, F.R.S., published in the Tutorial Series of the University Correspondence College. The volume is concisely and clearly written, and may be recommended as a useful text-book.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. R. Norton Stevens; a Yellow Baboon (*Cynocephalus babouin*, ♀) from Parrapatti, Eastern Coast of Africa, presented by Mr. J. V. Williams; a Kinkajou (*Cercoleptes caudivolvulus*, ♀) from Demerara, presented by Mr. Sydney Matthews; three Alligators (*Alligator mississippiensis*) from Florida, presented by Mr. Ernest H. Shackleton; two Green Turtles (*Chelone viridis*) from Ascension, presented by Commander Duncan Campbell; a Common Viper (*Vipera berus*), British, presented by Mr. A. Old; a Macaque Monkey (*Macacus cynomolgus*) from Java, a Lion (*Felis leo*, ♂) from India, a Sooty Phalanger (*Phalangista fuliginosa*, var.) from Tasmania, a Larger Hill Mynah (*Gracula intermedia*) from Northern India, a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, a Derbian Sternothere (*Sternotherus derbianus*) from West Africa, three South American Rat Snakes (*Spilotes variabilis*) from South America, deposited; a Blossom-headed Parrakeet (*Palaeornis cyanocephalus*) from India, a Tuberculated Iguana (*Iguana tuberculata*) from the West Indies, purchased; three Pumas (*Felis concolor*), eight Black Salamanders (*Salamandra atra*), born in the Gardens, two Triangular-spotted Pigeons (*Columba guinea*), two Crested Pigeons (*Ocyphaps lophotes*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE ROTATION OF VENUS.—Since our note last week on this subject, Signor G. Schiaparelli has published in the *Astronomische Nachrichten* (No. 3304) two letters concerning markings observed on the planet in July, and their bearing upon the question of rotation. The planet was observed from July 3 to 8 under all kinds of conditions, and the conclusion arrived at was that "the aspect of the dusky markings distributed over the disc did not undergo any important modification in form or situation during this period. Save a few small exceptions, all the variations

observed belong to the category of those apparent changes of diurnal period which may be explained by the varying state of rest and purity of the atmosphere and the different grades of illumination of the background of the sky. I have sought with particular care for an indication of any change of place of the most pronounced markings, with reference to the horns and with reference to the terminator; but I have not been able to make out anything with certainty which would indicate a more rapid rotation." This letter is accompanied by a sketch showing a marking diverging from the north pole, and another and more decided one proceeding from the terminator near the south pole in an easterly direction, and then curving round towards the north in the direction of a meridian. This marking underwent some slight change between July 5 and 7, the marking along the meridian only appearing on the latter date. In conclusion, Schiaparelli observes that the period of 224·7 days appears to be placed beyond all reasonable doubt. The second letter, written after the publication of Brenner's observations, contains a detailed description of Brenner's great marking, which is identical with the marking just described, and also with that observed in December 1877. Schiaparelli remarks that the view, advanced by him in "Considerazioni sul moto rotatorio del Pianete Venere," that the markings, though in reality atmospheric phenomena, depend to a certain extent upon the topographical conditions underneath, and recur under the same conditions, appears to be confirmed.

THE OBSERVATORY OF YALE UNIVERSITY.—The report of Dr. W. L. Elkin on the work done and in hand at the Observatory of Yale University, has been received. From the report we learn that the series of heliometer measures on the parallaxes of the first magnitude stars has been brought to a close, and the definitive results will be presented in the near future. The series on the parallaxes of the larger proper motion stars, on which Dr. Chase has been mainly engaged, now comprises 99 stars, all but two of which have been observed at two parallax maximum epochs, in general on three nights. Before drawing any conclusions from these data, it is proposed to secure two further epochs for each star, in order to eliminate the effect of the proper motion. An arrangement has been made with Dr. Gill that the observations and discussion of the *Iris* series for the determination of the solar parallax should be printed and included with his similar investigations on *Victoria* and *Sappho*. For the photography of meteor trails, an equatorial mounting, to carry a number of cameras, has been constructed and set up. The mounting carries four cameras, two with lenses of about 6 inches, and two with lenses of about 5 inches effective aperture. Some valuable results will, undoubtedly, be obtained from the photographic data accumulated by instruments of this kind. Already the Yale Observatory is in possession of some twelve impressions of Perseid trails, four of which were secured there and two at Ansonia by Mr. John E. Lewis, working in collaboration with Dr. Elkin. Prof. Barnard has sent three plates exposed also on August 9, 10, and 11, 1894, for about 8 hours in all, which show four and possibly five meteor trails. And Prof. Pickering has found on an examination of the Harvard Observatory plates one fine trail on a plate taken August 8, 1893, and sent it to Yale for measurement. Dr. Elkin has carried out a discussion of these trails, which will be very shortly ready for publication, and seems to lead to some interesting conclusions.

THE NEBULA N.G.C. 2438.—The first of a new series of celestial photographs, taken by Dr. Isaac Roberts, appears in the current number of *Knowledge*. It is a photograph of a portion of the constellation Argo, and shows the beautiful cluster M 46, and the involved nebula N.G.C. 2438. The nebula is a very small one, and was classed as a planetary nebula by Sir John Herschel; Lord Rosse, however, on some occasions, observed it as an annular nebula with two stars and a suspected third one enclosed; Lassell described it as a planetary nebula with two stars involved. The photograph, which was exposed for 90 minutes in the 20-inch reflector, shows the nebula to be as perfectly of the annular type as that in Lyra. It is circular in form, with three stars in the interior, the ring being most condensed on the north following side. The brightest star is near the centre, and is estimated at from 13th to 14th magnitude; on the south preceding side is a star of about 16th magnitude, and a still fainter one almost touches the ring on the south preceding side. There are indications of faint luminosity in the interior of the ring.

The cluster depicted in the same photograph is a "magnificent aggregation of stars between the 9th and 16th magnitude."

THE VOYAGE OF THE "ANTARCTIC" TO VICTORIA LAND.[1]

ALLOW me first to explain that my scientific observations were made under the disadvantageous circumstances of a sailor before the mast on board the whaler *Antarctic*. There seemed no choice between adopting this course and remaining on shore, and I was consequently able to take very few instruments. This explanation may to some extent lighten the criticism of my results.

We left Melbourne on September 20, 1894. It was originally our intention to spend a few weeks in search of sperm whales off the south-west of Tasmania; but not meeting with any, we steered for Royal Company Islands. On October 18 we had snow on board for the first time. It came in heavy squalls, bringing a large specimen of the *Diomeda exulans* albatross on board for refuge. At night it was moonlight, and at twelve o'clock the Aurora Australis was visible for the first time, with white shining clouds, rolling from west to east, at an altitude above the southern horizon of thirty-five degrees. The *Antarctic* was at the time in the vicinity of Macquarie Island, in latitude about 50° south. The aurora seemed to be constantly reinforced from the west, the intensity of the light culminating every five minutes, dying out suddenly, and regaining its former brilliancy during the succeeding five minutes. The phenomenon lasted until two o'clock, when it was gradually lost in an increasing mist. As the snow was heavy, and there was little probability of any material benefit from landing, we set out for Campbell Island on the 22nd, and dropped anchor in North Harbour on the eve of October 25, drifting the following day down to Perseverance Bay, a much safer harbour, where we filled our water-tanks and made final preparations before proceeding south. Campbell Island shows from a great distance its volcanic origin and character, undulating ridges rising in numberless conical peaks to from 300 to 2000 feet above sea level. The land around the bay is rich in vegetation, and most of the island is covered with grass, on which a few sheep seem to live in luxury. Numerous fur seals were basking on the rocks, and we also found many sea-leopards (*Stenorhynchus leptonyx*). They seemed to thrive well, their skins being without scar or cut, and, except human beings, they appear to have no enemies in these waters.

While duck-shooting on the Campbell, I came on three graceful waders of the snipe type (*Novæ Zealandiæ*). In the interior of the island grass was everywhere to be seen except where stunted brushwood covered the ground. I have no doubt that some of the hardy species of Scandinavian trees would do well on this island.

We weighed anchor on October 31. During the next few days, proceeding further into the fifties, the air and water remained at an equal temperature of 44° F. A large number of crested penguins were seen jumping about like small porpoises. We met with several icebergs from 100 feet to 150 feet in height. These bergs were solid masses of floating ice, with perpendicular walls and an unbroken plateau on the top.

On the 6th of the following month, in lat. 58° 14′ and long. 102° 35′, we sighted an immense barrier of ice, or chain of icebergs, extending for about forty to sixty miles from east to north-west, in fact as far as the eye could reach, the top being quite level and absolutely white, and the greatest height 600 feet. The perpendicular sides were dark ashy grey, with large worn green caves. Several icebergs, similar to those we had encountered before, were floating in all directions, and were undoubtedly children of this enormous monster.

By the time we had reached 55° the albatross had left us, as likewise the Cape pigeon (*Daption capensis*); but the white-bellied storm petrel still followed in our track. A lestris, with dark brown head and white bordered wings, and a small blue petrel put in an appearance. On December 7 we sighted the edge of the pack ice and shot our first seal, which was of the white kind (*Stenorhynchus carcinophaga*), its skin being injured by several deep scratches. We had also a very heavy snowfall, the vessel being covered on deck and rigging for the first time.

On December 8, in lat. 68° 45′, long. 171° 30′, large streams of ice drifting around us, a strong ice blink appearing towards the south, and the presence of the elegant white petrel (*Procellari Nivea*) gave us unmistakable evidence that we had now before us those vast ice-fields into which Sir James Ross successfully entered with his famous ships *Erebus* and *Terror*, on January 5, 1841. In the evening we slowly worked our way in

[1] Abstract of a paper read by Mr. C. E. Borchgrevink at the Sixth International Geographical Congress on August 1.

through the outer edge of the ice-pack, which consisted of large and heavy hummocky ice. I saw multitudes of the *Argonauta Antarctica* everywhere in the pack, usually swimming in cavities in the ice-floes to escape their enemies the whales. The large-finned whale (*Physalus Australis*) was spouting about in all directions. The white petrels were numerous here, and I secured more of them. The white-bellied petrel departed at the edge of the pack, leaving the icy regions to its darker, hardier brethren (*Thalassidroma Wilsonii*). We shot several seals, but they were scattered about sparsely, most having scars and scratches in the skin. Sir James Ross noticed similar wounds on the seals, and it has been supposed that they are inflicted by the large tusks in battle between themselves. My opinion, however, is that these scars must be ascribed to the action of a different species. The wounds are not like those inflicted by a tusk, being from two to twenty inches in length, and straight and narrow in shape, and where several are met with on the same animal, they are too far apart to have been produced by the numerous sharp teeth of the seal. Nor do I consider that they are due to the sword-fish, though that is doubtless doing mischief there. If my opinion, that these wounds are inflicted by an at present unknown enemy of the seal, proves correct, it may serve to explain the strange scarcity of these animals in regions where one would expect to find them almost everywhere.

When we entered the ice-pack the temperature of the air was 25° F., that of the water 28° F., which latter temperature was maintained all through the pack. Penguins were about in great numbers.

On the 14th we sighted Balleny Island, finding it in lat. 66° 44′, long. 164°: this agreeing with Ross. The ice-floes became gradually larger as we approached land, and it was evident that the ice-pack then around us was in great part discharged from the glaciers of Balleny, some of it carrying stone and earth. Although the higher part of the island was lost in mist, we got a good view of its lofty peak, which rises to a height of 12,000 feet above the sea level. The size and shape of the ice about Balleny was a source of considerable danger to our vessel, covered as it is with snow to a depth of several yards, and running out under water in long sharp points. It is not likely that a vessel depending entirely on sails would long survive in such ice. The air temperature at Balleny was found to be 34° F., that of the water 28° F.

Finding the pack so impenetrable in this locality we resolved to work eastwards, in the track which the *Erebus* and *Terror* had followed. On December 22, in lat. 66° 3′, long. 167° 37′ E., I shot a seal of ordinary size and colour, but with a very thick neck, and no sign of scars, a kind which none of our old sealers on board had ever seen before.

On Wednesday, the 26th, we crossed the Antarctic circle, and on New Year's Eve were in lat. 66° 47′, long. 174 8′ E. at twelve o'clock. In lat. 67° 5′, long. 175° 45′ E., I secured a specimen of *Aptenodytes Forsterii* a large penguin. I only secured four of these birds altogether, and never saw it in company with others of its kind. On the 14th, in lat. 69° 55′ and 157° 30′ E., we came again into open water, having spent 38 days in working our passage through the ice-pack. A clear open space of water was now before us. We steered straight for Cape Adare on Victoria Land, and sighted it on the 16th of January. On the 18th, in lat. 71° 45′, long. 176° 3′ E., the temperature of the air was 32°, and of the water 30°. The cape, which is in 71° 23′ and 169° 56′ E., rises to a height of 3779 feet, and consists of a large square basaltic rock with perpendicular sides. From there we saw the coast of Victoria Land to the west and south as far as the eye could reach, rising from dark bare rocks into peaks of perpetual ice and snow 12,000 feet above the sea level, with Mount Sabine standing out above the rest. I counted as many as twenty glaciers in the immediate vicinity of the bay, one of which seemed covered with lava, while below a layer of snow appeared another layer of lava, resting on the surface of the glacier. A volcanic peak about 8000 feet in height had undoubtedly been in activity a short time before. On the 18th we sighted Possession Island, and effected a successful landing on the North Island, being the second to set foot on this island, Sir James Ross having preceded us fifty-four years before. The island consists of vesicular lava, rising in the south west into two pointed peaks 300 feet high. I scaled the highest of these, and called it Peak Archer, after A. Archer, of Rockhampton, Queensland. To the west the island rises gently upward, forming a bold and conspicuous cape, to which, not having been christened by Ross, I gave the name of Sir Ferdinand von Mueller. I quite unexpectedly found vegetation on the rocks about 30 feet above the sea level, vegetation having never been discovered in so southerly a latitude before. We gave to this island, which I judged to be about 300 to 350 acres in extent, the name of Sir James Ross Island. Possession Island is situated in lat. 71° 56′, long. 171 10′ E.

On January 20 we steamed southwards, and on the 21st sighted Colman Island at midnight. Finding the eastern cape of this island unnamed, we called it Cape Oscar, in honour of his Majesty our King. I noticed great irregularities in our compass at Colman Island, and undoubtedly it contains secrets of scientific value. On the 22nd, being in lat. 74° S., and no whales appearing, it was decided to head northwards again, although all regretted that circumstances did not permit of our proceeding further south.

On the 23rd we were again at Cape Adare. Icebergs of large size were everywhere to be seen, and showed distinctly whether they were broken from the big barrier or discharged from the glaciers on Victoria Land. We landed at Cape Adare that night, being the first human beings to put foot on the mainland. Our landing-place was a kind of peninsula or landslip, gently sloping down from the steep rocks of Cape Adare until it ran into the bay as a long flat pebbly beach. The peninsula formed a complete breakwater for the inner bay. The penguins were, if possible, even more numerous here than on Possession Island, and were found in the cape as far up as 1000 feet. Having collected specimens of the rocks, and found the same cryptogamic vegetation as on Possession Island, we again pulled on board. We now stood northward, and in lat. 69° 52′, long. 169° 6′ E., again ran into the ice-pack. On February 1, in lat. 66°, long. 179° 31′ E., we reached open water, having this time spent only six days in the ice-pack. On the 17th the Aurora appeared stronger than I ever saw the Aurora Borealis. It rose from south-west in a broad stream towards the zenith, and down again towards the eastern horizon, being quite different in appearance from when we last saw it on October 20. It presented long shining curtains rising and falling in wonderful shapes and shades, sometimes seemingly quite close to our mastheads, and it evidently exerted considerable influence upon our compass-needle. In lat. 44° 35′ and long. 147° 34′ we met with a great number of sperm whales. After struggling for several days with a furious storm of distinctly cyclonic character, we sighted the coast of Tasmania on March 4, and entered Port Philip on the 12th, five months and a half after our departure from Melbourne.

As my report shows, we had comparatively high temperatures during our voyage, higher than Sir James Ross experienced, and higher than those observed last year by the whaling fleet south of Cape Horn. The minimum temperature we experienced within the Antarctic circle was 25° F., the maximum 46°. The average temperature from 200 readings each month was 32°.5 for January, 30° for February. The temperature of the water remained at 28° F. all through the ice-pack, rising 1° wherever a larger sheet of water broke the ice-fields. In the large bay in South Victoria Land the temperature remained nearly constantly about freezing-point. The question naturally arises: Has the average temperature at the shore of Victoria Land risen during the last fifty-four years, and has vegetation for the first time developed in those southern latitudes since Ross was there? It does not seem probable that the appearance of vegetation on Possession Island would have escaped the observation of the naturalists who accompanied that expedition. It is evident that a warm current with a constant direction northwards breaks the ice-fields at the very place where Sir James Ross and we penetrated to the open bay of Victoria Land. Within the Antarctic circle the barometer at 29 inches always indicated calm, clear weather, and even at 28 inches it remained fine. This low barometric reading is remarkable considering the dryness of the air. The prevailing wind in the bay seemed to be from the east, but at Cape Adare a change appeared to take place, and westerly winds are there, to all appearance, predominant. The direction of the movement of the ice is distinctly north-easterly, and the scarcity of ice in the bay of Victoria Land is undoubtedly not alone due to warm currents, but also to the protection from drift ice afforded by the shore from Cape Adare down to the volcanoes Erebus and Terror.

The rocks on Possession Island seem all to be of volcanic origin, and represent basaltic lava flows which have taken place during late geological epochs. The specimens I brought from South Victoria Continent differ but little from those I found on Possession Island. One peculiar rock I collected has an indistinct granular structure, and resembles much the garnet sand-

stone of Broken Hill; it seems to bear some close relation to granitite. The specimen is composed of quartz, garnet, and felspar fragments. This rock holds out hopes that minerals of economic value may occur in these regions.

The peninsula on which we landed at Cape Adare must be some seventy acres in extent: on the top of the guano were lying the primitive nests of the penguins, composed of pebbles. Some hundreds of yards up these landslips I came upon two dead seals, which from their appearance must have lain there several years. I made a thorough investigation of the landing-place, because I believe it to be a place where a future scientific expedition might safely stop even during the winter months. Several accessible spurs lead up from the place where we were to the top of the cape, and from there a gentle slope leads on to the great plateau of South Victoria Continent. The presence of the penguin colony, their undisturbed old nests, the appearance of the dead seals, the vegetation on the rocks, and, lastly, the flat table of the cape above, all indicated that here the unbound forces of the Antarctic circle do not display the whole severity of their powers. Neither ice nor volcanoes seemed to have raged at the peninsula at Cape Adare, and I strongly recommend a future scientific expedition to choose this spot as a centre for operations. At this place there is a safe situation for houses, tents, and provisions. I myself am willing to be the leader of a party, to be landed either on the pack or on the mainland near Colman Island, with Ski, Canadian shoes, sledges, and dogs. From there it is my scheme to work towards the south magnetic pole, calculated by Ross to be in 75° 5′ and 150° E., Colman Island lying in 73° 36′ S. and 170° 2′ E. I should have to travel about 160 miles to reach the south magnetic pole. Should the party succeed in penetrating so far into the continent, the course should be laid, if possible, for Cape Adare, in order to join the main body of the expedition there.

As to the zoological results of future researches, I expect great discoveries. I base my expectations on one point—on the scars found on the seals, which in my opinion point to the existence of a large unknown mammal within the Antarctic circle. Although the white polar bear of the Arctic has never been found in the south, I should not be surprised to discover similar species there. It would indeed be remarkable if, on the unexplored Victoria Continent—which probably extends over an area of 8,000,000 square miles, or about twice the size of Europe—animal life hitherto unknown on the southern hemisphere should not be found.

It is of course possible that the unknown land around the axis of rotation may consist of islands, only joined by perpetual ice and snow; but the appearance of the land, and the colour of the water with its soundings, in addition to the movements of the Antarctic ice, point to the existence of a mass of land much more extensive than a mere island.

It is true that the scientific results of this expedition have been few, but my little work gives me at least the satisfaction of feeling that it will fill a useful, if molecular, place among those strong arguments which for years have accumulated, and which prove that further delay of a scientific expedition to South Victoria Continent can scarcely be justified.

WEATHER FALLACIES.[1]

IN the long and patient pursuit which the attainment of all accurate knowledge exacts from man, it may sometimes be instructive to turn one's gaze backward and contemplate the errors which have been corrected, the fallacies which have been demolished, and the superstitions which have been lived down; and this consideration has prompted me to take for the subject of this year's address that wide range of human opinions which may fitly be classed under the head of "Weather Fallacies."

Nothing could have been more in accordance with the law of growth in other branches of knowledge than that Meteorology should, in its earliest dawn, have been with difficulty able to emerge from the mists and darkness of guesses and surmises such as have surrounded the transfer of any truth from the barbaric to the philosophic stage.

It is to the Greeks that we must look for the first real weather observations after the matter had passed through what may be called the mere savage phase: and we find Hesiod, Theophrastus, and Aratus presenting us with an early code of rules, which serve at least to show us how little we have ourselves advanced in some matters since their time.

[1] An address delivered to the Royal Meteorological Society, by Mr. Richard Inwards, President. (Reprinted from the *Quarterly Journal* of the Society.)

One of our Fellows, Mr. J. G. Wood, has just given to the world an excellent and scholarly translation of the work of Theophrastus, which has not previously been put in an English garb, and Mr. Wood has done the whole country a great service in giving us this translation of the "Winds and Weather Signs," a book which contains a host of rules and observations about the weather, and which, as might have been expected from the production of the favourite pupil of Plato and Aristotle, is singularly free from errors of the grosser and more superstitious kind, such as were plentifully produced in Western Europe many centuries later.

But long before the time of Theophrastus, and probably very soon after the invention of agriculture itself, there were weather gods and weather fallacies; for we find that Jupiter Tonans and Pluvius—the thunderer and the rain-maker—were set by men on the highest pedestals. And centuries after this, Lucian tell us that it was usual in his time to offer prayers for suitable weather, and he recounts in his "Dialogues" how two countrymen were at the same time offering up contrary petitions—one that not a drop of rain might fall until he had completed his harvest, while the other prayed for immediate rain, in order to bring on his backward crop of cabbages—both suppliants only too sure to find that the ears of the image were deaf as the stone of which they were made, and that the wheels of the universe would not wander or turn back for any selfish ends of man.

In considering these early times, when the weather had to be studied from cloud, sky and sea, and from the behaviour of the animals and plants, we must be ready to excuse men for doing that which is still too frequently a cause of error, viz. foretelling what they most wished for, and putting down as universal law that which was only a coincidence of totally independent events. In considering weather fallacies it will be impossible to follow a chronological order, so I shall treat them, or rather a small portion of them, under the heads of saints' day fallacies, sun and moon fallacies, and those concerning animals and plants, while finally I shall consider the almanack makers, weather prophets and impostors who have from time to time furnished the world with materials for its credulity or its ridicule.

The first class of weather fallacies which I shall scarcely more than mention, are those which refer to the supposed connection between the weather of any day in the week or year, and that of any other period, and it may be as well to state at the outset that there is no kind of foundation in fact for any of these so-called rules. They are for the most part born of the wish to see certain kinds of weather at certain times of year, and, like all these predictions, were faithfully remembered when they came true, and promptly forgotten when they failed. One has often heard—

"Fine on Friday, fine on Sunday."

Or that "Friday is the best and worst day of the week," and the superstition even extends to hours of the day, for we have

"Rain at seven, fine at eleven,"

which is only another way of saying that rain does not usually last four hours, and the rule generally fails when applied to daily experience; but the host of proverbs connected with saints' days are more difficult to deal with, on account of the longer time which elapses between the prophecy and its fulfilment or failure. All or most of these proverbs concern the days of certain saints, though I think no one imagines that this is anything more than a convenient method of fixing the date, because our ancestors had a saint for every day, so that they naturally referred to the day by his name.

There are forty weather saints, among the most prominent of whom is undoubtedly St. Swithin, whose day is July 15, and the superstition is that if it should rain on that day it will rain for forty days after. Now, as Mr. Scott observes, this date is very near a well-known bad time in wet years, as the terms, long in use, of "St. Margaret's flood" and "Lammas flood" abundantly testify. The fact that some of these heavy rains began on July 15 has been enough material for the adage-monger, and so we have another "universal" law laid down, a law which is, however, constantly broken, as every student of the weather very well knows. The whole thing is a fallacy of the most vulgar kind, and ought speedily to be forgotten, together with all the adages which make the weather of any period depend on that of a distant day.

Turning in weariness from this class of superstitions, which may be said to belong to the self-exploding order, we are next met by an extensive array of authorities who, under the protecting

shield of astronomy, profess to have framed infallible rules for the weather as judged from the ever-varying relative positions of the sun, moon, and planets. They attack us systematically and persistently, appealing to analogy, to reason, and to common sense. But it is sometimes necessary to be on our guard, even against common sense, in considering problems to which uncommon sense has for centuries been devoted without avail. The well-known action of the sun and moon upon the ocean tides is generally the starting point of these theorists, and it is soon shown to common sense that when the earth is nearer the sun, or the moon is nearer to the earth (it being remembered that they move in elliptic orbits), or when both sun and moon are, as it were, pulling together, as at new moon, there ought to be a tide of atmosphere caused by their influence similar to the tides of the ocean, which such agencies undoubtedly produce. But we find that whatever so-called reason, analogy, and common sense may seem to dictate, the facts will not follow in the path marked out for them; and the atmospheric tides refuse to ebb and flow, except in a most infinitesimal degree, quite disproportioned to their supposed moving forces. The theorists must try again, and they do so by pointing out that the moon and earth move in planes which are inclined to each other at an angle, and that at some times of the year the attraction of the sun and moon are acting in somewhat widely diverging lines, whilst at others they are pulling more nearly in the same plane. Here is, they say, a clear case. At times, when the angle is greatest, there should at any rate be worse weather caused by the conflicting forces. When the moon is said to be "on her back," or, in other words, when the line of the shadow boundary of the half-moon or crescent is much inclined to the earth's axis, then is the time, say they, for tempests and commotions to come. But again the spirits from the "vasty deep" do *not* come when called, and we have to invent other causes for our earthly disturbances.

It may be safely said that a new moon theory as to the weather comes out at least once a year, and it has been attempted to connect the honoured name of Sir William Herschel with a table which professed to show the dependence of weather changes on those of the moon.

By the kindness of Mr. Symons I am able to show you on the screen a much magnified representation of this production, now very scarce, and which has the name of Herschel in large capitals, no doubt as a sort of ballast to give it weight and steadiness, though it does not definitely state that Herschel had anything to do with it. Herschel's own letter on the subject runs as follows:—

Sir

I am glad of an opportunity to say that prognostications of the weather are so much above the knowledge of astronomers that I have taken uncommon pains publicly to contradict reports of predictions that have been ascribed to me. You may therefore be assured that what you have heard of my opinion about the frost is without the smallest foundation. If at any time Slough should be in your road, I shall be very glad to see you here, and remain

Sir

your most obed^t
Serv^t

Wm Herschel

Slough
near Windsor
Feb 6 1814

So that any fellow of the Society who sees one of these diagrams in the future will know it as a fraud.

Of course it is in the power of every one to check the predictions which are so often made with respect to the changes of the weather taking place on the change of the moon; but many eminent men have occupied themselves with the subject, and the result is that no correspondence between the two classes of phenomena has been established.

Dr. Horsley examined the weather tables of 1774, as published by the Royal Society, and out of 46 changes of weather in that year only ten occurred on the days of lunar influence, only two of them being at the new moon, and none at all at the full. M. Flarguergues, of Viviers, found also as the result of twenty years' observations, that the barometer readings taken when the moon was furthest from the earth averaged 755 millimetres, and when nearest, 754 millimetres, showing a difference of 1 millimetre or about ·04 inch, and this in a direction against the theory, the pressure being greater by that amount when the moon was farthest from the earth.

Various other weather seers have pinned their faith on lunar cycles, and have predicted that weather changes would repeat themselves, as soon as the sun and moon got back into the same relative positions, which they do in nineteen years, with only an error of an hour and a half. Others, such as Mr. G. Mackenzie, advocated a cycle of 54 years, but it may be summarily stated that all the cycles have broken down, and that, as far as we know, there is no definite period after which the weather changes repeat themselves.

Other fallacies about the moon are numerous, such as that the full moon clears away the clouds; that you should only sow beans or cut down trees in the wane of the moon; that it is a bad sign if she changes on a Saturday or Sunday; that two full moons in a month will cause a flood; that to see the old moon in the arms of the new brings on rain, and many others, of which a catalogue alone would take up a good deal of space. M. Flammarion says that "the moon's influence on the weather is negligible. The heat reaching us from the moon would only affect our temperature by 12 millionths of a degree; and the atmospheric tides caused by the moon would only affect the barometric pressure a few hundredths of an inch—a quantity far less than the changes which are always taking place from other causes." On the whole we are disposed to agree with the rhyme which thus sums up the subject:

> The moon and the weather
> May change together;
> But change of the moon
> Does not change the weather.

Even the halo round the moon has been discredited, for Mr. Lowe found that it was as often followed by fine weather as by rain, and Messrs. Marriott and Abercromby found that the lunar halo immediately preceded rain in 34 cases out of 61. We always have a lingering hope that some future meteorologist will disentangle the overlapping influences, and arrive some day at a definite proof that our satellite after all has something to do with our weather.

About the sun, also, there are many fallacies, and ever since the discovery that the spots which appear on his surface have a period of greatest and less frequency, there have been theorists in shoals who have sought to prove that this fact rules our weather. It has undoubtedly been found that the frequency of sun-spots and the variations of the magnetic needle are intimately connected; and it is almost equally well established that the aurora appears and disappears in some sort of sympathy with the sun-spot variations. But this, up to the present, is as far as we can get in this direction, for our weather seems to have no definite relation to these changes.

The more recent discoveries of prominences visible round the disc of the sun during an eclipse, and of the light clouds only seen in M. Deslandres' spectro-photographs, will no doubt call out new weather theories on the subject. And I must confess to a wish that those mysterious flame-like bodies rushing from the sun millions of miles into space, will be found to have some influence on the upper layers of our earth's atmosphere; but I also hope that we may be saved from a theory on the subject until more facts are before us.

Coming down to earth again, we are met by a long array of fallacies connected with the behaviour of animals and plants, and which have a supposed connection with weather changes. Few of these are so well grounded that they may be considered as proved, and as nothing is sacred to a meteorologist, our veteran

Fellow, Mr. E. J. Lowe, F.R.S., has endeavoured to put some of the rules from this source to the test of definite observation. He took a number of well-known signs said to indicate change, and carefully noted what happened after each sign, and although he does not say that all indications from animals, birds and plants are useless, yet certainly those he did investigate seemed utterly to break down.

He took the well-known signs of bats flying about in the evening, many toads appearing at sunset, many snails about, fish rising much in lake, bees busy, many locusts, cattle restless, land-rails clamorous, flies and gnats troublesome, many insects, crows congregating and clamorous, spider-webs thickly woven on the grass, spiders hanging on their webs in the evening, and ducks and geese making more than usual noise. Mr. Lowe found that in 361 observations of the above signs, they were followed 213 times by fine, and only 148 times by wet weather; so that even after the prognostications for rain, there was a greater preponderance of fine weather. He called a day fine when no rain was measurable in the rain gauge. Mr. Lowe says that even swallows flying low cannot be depended on, as, especially at the close of summer and autumn, they almost invariably skim the surface of the ground, and Mr. Charles Waterton, the naturalist, decided, after careful observation, that the unusual clamour of rooks forms no trustworthy sign of rain. These must, therefore, swell the list of fallacies, although there are many other rules which have not been so carefully examined, but which may still be true. My own impression is that although it is painful to dismiss the animals from their ancient position as weather prophets, we may consider them as indicating what they feel, rather than as predicting what is to come, and that their actions before rain simply rise from the dampness, darkness or chilliness preceding wet weather, and which render these creatures uneasy, but not more so than they affect man himself. The sheep turning its back to the wind (one of the best known signs of rain) is probably only that it may shelter its least protected part from the effects of the weather; and many of you must have observed sheep sheltering their heads from the heat by getting them into the shade of each other's bodies in a similar way.

As to cows scratching their ears, and goats uttering cries, and many other signs of bad weather, they are at least very doubtful; whilst the adage about the pig which credits him with seeing the wind, carries with it its own condemnation.

The medicinal leech is still left on the list of weather prophets, though he has no doubt had his powers exaggerated; and two books have been written about his behaviour during changes of weather. One is by Mrs. Woollams, who, during a long illness, watched a leech in a bottle, and carefully noted what it did; and the other is by a gentleman at Whitby, who came to the conclusion that the leeches could be made to give audible and useful storm warnings. So he contrived the instrument, of which I now show you a drawing taken from his book. No one would imagine from its appearance what its use could be. It consisted of twelve glass bottles each containing a leech in water, and so arranged in a circle, in order, as the humane inventor states, that the leeches may see each other and not endure the affliction of quite solitary confinement—this rather reminds us of Isaac Walton, who told his pupil to put the hook into the worm "tenderly, as if he loved it"—in each bottle was a metal tube of a particular form, and which was made somewhat difficult for a leech to enter, but into which it would endeavour somehow to creep before a thunderstorm, according to its nature. In each tube was a small piece of whalebone, to which a gilt chain was attached, and so arranged, on the mouse-trap principle, that when the whalebone was moved the bell at the top of the apparatus was rung by means of the chain. There were twelve leeches, so that every chance was given that one at least would sound a storm signal. The author called this apparatus the "Tempest Prognosticator," a name which he preferred—and I think we shall agree with him—to that of atmospheric electric telegraph conducted by animal instinct. He went on to state in his little book that he could, if required, make a small leech ring the great bell of St. Paul in London as a signal of an approaching storm. The book is written in all seriousness, and a number of letters are appended from gentlemen who certify that correct atmospheric indications were at various times given by the leeches. The name of the inventor of this ingenious contrivance was Dr. Merryweather—himself a learned leech.

Plants have also their advocates as weather indicators; and there is no doubt that in most cases they act in sympathy with changes in the dampness, gloominess, or chilliness of the air, and as these conditions generally precede rain, one cannot term the indications altogether fallacious. The pimpernel and the marigold close their petals before rain, because the air is getting damper, while the poplar and maple show the under surface of their leaves for a similar reason. Indeed, an artificial leaf of paper may may be made to do the same thing, if constructed on the same principle as the natural one—a hard thin paper to represent the upper side of the leaf, and a thicker unsized paper for the lower side; these will, if stuck together, curl up or bend down in sympathy with the hygroscopic condition of the air. A slip of ordinary photographic paper will do the same, and will curl up at once when placed on the hand.

The same slackness which moisture produces in plants applies in some degree also to insects, some of which can only fly in sunshine, so that there is a chain of weather signs all following from a little dampness in the air. The flowers close their petals and shut in their honey, the insects cannot fly so high, and the swallows seeking them skim the surface of the earth, and even then the threatened shower may not come.

In 1892 attention was directed to a plant, the *Abrus precatorius*, a beautiful shrub of the mimosa kind, which has the property of being sensitive in a high degree, so that its pinnate leaflets go through many curious movements, and it was claimed that these form a guide of unerring certainty to foreshow the coming weather. Even earthquakes were said to be predicted by this wonderful plant. If it closed its leaflets upward, after the manner of a butterfly about to settle, fair weather was shown; when the leaflets remained flat, changeable and gloomy weather was indicated; while thunder at various distances was to be foretold by the curling of the leaflets, and the nearer the thunder the greater the curl, until when the points of the leaflets crossed, the thunderstorm was indicated as being overhead. Changes of wind, hurricanes, and other phenomena were to be shown by the various curious and beautiful movements of the leaflets and stalks. These movements undoubtedly took place, but when the plant was submitted to the unprejudiced observation of Dr. F. W. Oliver and Mr. F. E. Weiss, at Kew Gardens, those gentleman failed to find any connection between these movements and the weather, and Dr. Oliver made a report on the matter, which hits the heart of the whole subject of plant movements, by ascribing them for the most part to the agency of light and moisture. Mr. Scott, of the Meteorological Office, gave the finishing stroke to the theory by proving that the movements had no connection with either cyclones or with earthquakes, so that the sensitive plant may be considered as out of the list of weather guides, in spite of having been made the subject of an English patent.

It is a most common observation in the country that a large crop of hips, haws, and holly-berries indicates a severe winter to follow, and it is generally pointed out that nature thus provides winter food for the birds. This, too, is a fallacy.

Another weather fallacy, for which artists are responsible, is that flashes of lightning take the form of long angular lines of a zigzag shape, and of which I show you an example, taken from a work on the subject. This, when compared with the next view, which is a photograph taken direct from nature, shows that the artist had very little understood the true form of the lightning flash, which consists of numbers of short curves joining each other, something like the course of a river depicted on a map, or in some degree like the outline of a clump of leafy trees seen against the sky. But, as far as I know, there were only two artists whose acute vision saw lightning in anything like its true form. One was Turner, who long before the time of photography, scratched his lightning flashes with a penknife, making short curved dashes across the picture; and the other was Nasmyth, the astronomer and engineer, who also saw the lightning in its true form, and duly noted the same, only to be confirmed years afterwards, when it became easy to photograph the lightning flash itself. While on the subject of lightning, I may mention that it is recorded that in one case at least a rheumatic man who had been confined to bed six weeks, received a shock from a stroke of lightning, jumped from his bed, and ran down stairs completely cured. This is related in the *Gentleman's Magazine* for June 1820.

It has been often stated that the noise of cannon will produce rain, and it is not unusual in the Austrian Tyrol to hear the church bells ringing to avert thunder. These are fallacies. The experiments in America made recently to test whether rain could be produced by exploding a large quantity of gunpowder in the air, resulted in nothing except noise and smoke, though the thing was well worth trying.

Empedocles of old is credited with the invention for chasing

away the Etesian winds by placing bottles made of the skins of asses on the hills to receive them. Timæus relates this. After hearing this about Empedocles, one is not surprised to learn that he thought there were two suns, that the moon was shaped like a dish, and that the sea was the sweat of the earth burnt by the sun. All this will be found in Stanley's "Lives of the Philosophers."

Almost in our own time, too, a "pluvifuge," or machine for blowing away rain, was proposed in Paris. This, too, was a fallacy.

To give an account of all the various ceremonies in savage and civilised countries which have been resorted to for the purpose of changing the course of the weather, would be here impossible; but such rites have a common origin and a common result. They begin in error, and end in failure. In India, the rain-god is imagined to pour down showers through a sieve: in Peru there was supposed to be a celestial princess, who held a vase of rain, and when her brother struck the pitcher, men heard the shocks in thunder. In Polynesia rain comes from the angry stars, stoning the sun; while in Burmah it is still the custom to haul down rain by pulling at a rope. New Caledonia has its regular rain-making class of priests, and in Moffatt's time the rain-makers of South Africa were held in even higher estimation than the kings; and on the other side of the world the Alaskan propitiates the spirit of the storm by leaving tobacco for him in a cave. In our own country, too, there have been weather witches of various grades, and one described in Drayton's "Moon Calf"

> "Could sell winds to any one that would
> Pay them for money, forcing them to hold
> What time she listed, tie them in a thread
> Which, ever as the seafarer undid
> They rose or scantled as his sails would drive
> To the same port whereat he would arrive.

The Finlanders at one time drove a profitable trade by the sale of winds. *After* being paid, they knitted three magical knots, and told the buyer that when he untied the first he would have a good gale; when the second, a strong wind; and when the third, a severe tempest.[1] Sir Walter Scott also mentions that King Eric, also called "Windy Cap," could change the direction of the wind by merely turning his cap round upon his head; and old Scotch women are mentioned who, for a consideration, would bring the wind from any desired quarter.[2] The Mandan Indian rain-maker had a rattle by the noise of which he called down rain from heaven by the simple process of keeping on long enough. It is safe to say that these are all fallacies.

From the rain makers we may now turn for a moment to the almanack makers, and any one who will look up an old almanack of the early part of the last century, will find the greater part of it filled with lucubrations on the influence of the stars and constellations; he will also find a column giving for every day the parts of the body which are particularly under the celestial influences on the given dates, and when one sees for the first time this column reading—head, chest, legs, knees, feet, &c., one wonders what it can mean; but it was then so well understood, as not even to require explanation, and there was generally too a rude woodcut of a hideous human figure, tattooed with the various signs of the zodiac to show the same thing. The sort of knowledge that passed for meteorology in 1703 may be learned from the following extract from "Meteorologia" by Mr. Cock, Philomathemat. 1703 a rare book in the possession of Mr. Symons.

"The twelve signs are divided into four sorts, for some be earthy, others watery, a third sort aery, and the fourth sort is fiery." The author then goes on to state that "Jupiter in the S[illegible]r (whatever that may be) opposed by Saturn in the Lion did raise mighty South west winds. . . . Observe when a planet is in an earthy sign he was lately dried up by perambulating a fiery sign, and after that, immediately having made his progress in an earthy sign, is quite bound up from moisture."

It seems incredible that our ancestors, only a few generations back, should have bought, paid for, and believed, such stuff as this. The early almanacks boldly gave a prediction for the weather for every day in the year; but after a time confined themselves to a general statement of the weather, for instance "Partridge's Almanack" for 1835 has the following prophecy for June: "Fertilising showers attended with thunder and lightning" [illegible] for the first ten days. "Fair and at times hot" for the middle of the month, and "refreshing rain for the grass and corn" for any time between the 21st and the end of the month.

Authors of weather almanacks had already begun to seek safety in vagueness. Some of these almanacks rose to a great popularity on the strength of one lucky guess; and I think it is told of this same Partridge's almanack, or some other of the class, that it owed its reputation to a curious prophecy of extraordinary weather for July 31, when hail, rain, snow, thunder, &c., were freely indicated. Forgetting that the month had 31 days the almanack maker had omitted to insert the weather prediction for the last day, and a boy was sent from the printing office to know how the space was to be filled up. The weather prophet was too busy to attend to him, but at last in a passion, said: "Put down hail, rain, snow, thunder, anything"; and the boy taking it literally told the compositor, who duly set into type the extraordinary prediction, and which by a freak of nature came true, and made the fame and fortune of the almanack maker. This story, if not true, is at least *ben trovato*, and shows the force of the bard's statement

> "Our indiscretion sometimes serves us well
> When our deep plots do pall."

The *British Almanack* for 1831, published by the Useful Knowledge Society, had no weather predictions.

Patrick Murphy published a popular weather almanack, and his fame is said to have commenced by a lucky hit in one of the earlier issues by which he indicated which would be the coldest day of the year. There is a copy of this almanack for 1838 in the library of the Society, and some former owner has evidently taken the trouble to pencil in the actual weather opposite to that predicted. There were, according to this annotation, 89 incorrect forecasts, 91 doubtful, and the rest correct.

This Patrick Murphy was not a mere charlatan. He had a system, and though he differed from Sir Isaac Newton and the Royal Astronomical Society, he gave much study and research to the subject of meteorology—as shown by his various books. There was an Astro-Meteorological Society as late as 1861, and we have some numbers of its *Records* in our library.

Next comes the subject of weather prophets as distinguished from mere almanack makers; and who profess, sometimes for pelf, at other times for honour and glory, to predict the weather for any future date. These are always arising, and they do not lack a certain number of followers, who, possessing a large angle of credence, duly trumpet forth the successes of their chiefs, when they are so fortunate as to make any. The stock-in-trade of a prophet is of a slender and cheap description. He must have an inventive mind, a store of self-confidence, an insensibility to ridicule, and, above all, a keen memory for his successes, and a prompt forgetfulness of his failures. He should by choice have a theory, and this should be of the elastic order, so that if a predicted event does not punctually occur, he will be ready with a sort of codicil to amend it. Hence we find that the firing of guns has been cited as a sufficient reason for falsifying a weather prediction; and railways, too, are said to have an adverse influence, one author (not a prophet) telling us that they may be considered as "large winnowing machines, perpetually fanning and agitating the air with prodigious power, ploughing the air, as it were, and causing waves of vast extent, which, invisibly enlarging like the waves of the ocean, probably meet each other, clash, and produce modified effects, as resultants from adverse motions."

One of the first weather prophets mentioned in that delightful old book, Stanley's "Lives of the Philosophers," was Democritus, the Milesian, known as the "laughing philosopher," who foresaw a dearth of olives, and by buying up all he could get might have made a fortune, but gave it back to the bargainers with the remark, "You can see now that a philosopher can get rich when he pleases." Then there was Pherecydes, of whom Pythagoras was a favourite pupil, who predicted an earthquake three days in advance by the taste of the water from a certain well. Perhaps the earliest of all was Elijah, who from the top of Carmel pointed out the coming squall cloud, and predicted a great rain. He forms a good model for imitation to the modern weather prophets, for he did not prophesy until he saw the storm coming, and he made no secret of his method. We have still amongst us in our country, mostly without honour, seers who supply us with weather predictions in various forms, from the modest duodecimo almanack to the flaring broadsheet which compels attention; but it would be a task too long to enter on a systematic refutation of their contradictory guesses at the weather. The last of these broadsheets that caught my eye had for the days of the gale of December 1894, which Mr. C. Harding has described to us, the tame announcement of

[1] [illegible]
[2] [illegible]

"generally overcast." This did not err on the side of boldness when considered with reference to one of the severest gales of the century.

A Spanish peasant whom I heard of in Andalucia, and who had the reputation of a weather prophet, wisely said, if you want to know the weather for to-morrow, ask me early in the morning. The Indian weather prophets who made a failure had to be silent altogether for the rest of their lives: and this causes us to regret that some of our own seers were not born in that distant land.

As to the so-called weather forecasts, they only come under the title of this paper when they fail, and as eight out of ten are said to be correct, I shall only say that they are honest attempts on the part of civilised governments to warn their people as far as possible against the march of known disturbances. I could wish that the term "weather indications" or "indicated weather" had been adopted, so as to make this plain to all, and that oftener, when the signs were vague, we had the simple announcement of no change indicated.

The director of this system so well known to us, and who is playfully called the "Clerk of the Weather," sometimes receives valuable hints, even from children: and I must quote one such communication.

"Please, Mr. Clerk of the Weather, tell the rain, snow, and hail to stop for the afternoon, and rain in the night."

I may conclude this section by saying that it is a great fallacy to suppose that there is such a thing as a weather prophet. All the great authorities agree that in the present state of our knowledge no human being can correctly predict the weather, even for a week to come.

And now we must consider a class of weather fallacies of which the victims can only excite in a well-regulated mind feelings of sadness and compassion, rather than the ridicule to which at first sight they seem more naturally entitled. I mean those weather prophets in whom the delicate mechanism of the mind is touched by disorder or decay, even if it has not already fallen under the stroke of complete dementia, and who believe that they can not only foresee the weather, but, by an effort of their own minds, control the elements and compel the clouds.

These patients I had hoped only existed in small numbers; but, on perusing the correspondence of a prominent meteorologist, kindly lent me for the purpose, I find that there are many of this class whose name, like that of the ancient wanderer among the tombs, is "Legion," and who still come on, each prepared to drive the chariot of the sun, or by an exertion of his own will, odylize (the word I suppose will come) all the powers of nature.

Dr. Johnson's Astronomer says in "Rasselas":—"Hear me, therefore, with attention. I have diligently considered the position of the earth and sun, and formed innumerable schemes, in which I changed their situations. I have sometimes turned aside the axis of the earth, and sometimes varied the ecliptic of the sun, but I have found it impossible to make a disposition by which the world may be advantaged. What one region gains another loses. Never rob other countries of rain to pour it on thine own."

This type of patient, as well as those who would use their supposed power for the purpose of creating fine weather during the holidays of the people, belong to the more noble sort, but there have been others, like the notorious Friar Bungay, who for sordid reasons have professed to exert a similar power. The only wonder is that anybody ever believed them.

Now, as this malady of the mind is not incurable, I will venture to offer a practical suggestion, and would recommend these patients who have nursed themselves into the belief that they possess the keys of the weather, to seek the hill-top on a summer afternoon—the air and exercise will do them good—and watch the fine fleeces of cumulus cloud as they sail majestically across the sky, each with its attendant shadow below. Let the patient concentrate his attention upon one single feathery cloud, and try by the exertion of his utmost force of will to make it pause for a moment in its career; and, if he fails—"as fail full well he may"—then let him banish from his mind for ever the idea that he can by his own will dominate the whole firmament. And if he has ever gone into print upon the subject, let him go home, and, like Prospero, his prototype, say

> "Deeper than ever plummet sounded,
> I'll drown my book,"

and so save the world from the trouble of investigating much pure nonsense. To these sufferers I can only repeat the words of one of our own kings to the last man he touched for the evil—"I wish you better health and more sense."

I must be forgiven for having only made a selection from the vast catalogue of fallacies which have accumulated about the subject, and I must continue to regret that there are still people who are ready to believe that the saints' days rule the weather, that the sun puts out the fire, that warm water freezes sooner than cold, or that a man is a prophet because he says so himself.

This Society is clearing the ground of many weeds, and already the fallacy of the "equinoctial" gales has been exploded (by Mr. Scott), while the churchyard ghost of the supposed fatal "green Christmas" has been most effectually laid by a recent statistical paper by Mr. Dines.

Some one may ask, after all this clearing away of fallacies—What have we left? and I would venture to refer him to all the patient work which is being done in various countries, and by which a real Science of Meteorology is being slowly built up, while to the outdoor weather student I would offer this consoling reflection—There is still the sky.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Prof. A. H. Church and Dr. Fream have been offered and have accepted Honorary Professorships at the Royal Agricultural College, Cirencester. These gentlemen were both formerly professors at the College, and both took part in the recent jubilee celebrations.

It would be a great advantage to the numerous students of science and technology if the scientific works in all public libraries were arranged in a separate class, and catalogued separately. This has been done for the Central Free Public Lending Library of Nottingham, by Mr. J. P. Briscoe, the librarian, and Mr. T. Dent. All the scientific books in the library have been arranged according to the science to which they refer, and indexed according to subjects and authors. The list will thus be of great assistance to students.

New technical schools, presented to Winsford, in the salt district of Cheshire, by Mr. Joseph Verdin, at a cost of £8000, were opened by the Duke and Duchess of Westminster last week. The money is part of a fund of £26,000, originally intended to compensate property owners from subsidences brought about by brine-pumping. As he was unable to transfer the fund, the Charity Commissioners were applied to, and it was decided that £12,000 should be used in the erection and endowment of technical schools at Winsford and Northwich.

Preceding a historical account of the Owens College, Manchester, contributed by Mr. P. J. Hartog to the current *Record* of Technical and Secondary Education, the function of university colleges in technical education is discussed. Mr. Hartog points to a fundamental distinction established by the Royal Commission on Technical Instruction between (1) institutions for the instruction of manufacturers and higher managers, and (2) institutions for the instruction of foremen and workmen engaged in industrial pursuits. He rightly remarks, however, that the distinction is still vague in the mind of the public, and even in that of many educationalists. It has become more vague through the use of the words "polytechnic" and "technical school" to render the German *polytechnicum* and *technische hochschule*, to which they are not at all equivalent. The *polytechnicum* and *technische hochschule* educate managers and manufacturers; our polytechnics and technical schools, with their day-schools for lads and their night-schools for adults occupied during the day, educate foremen and workmen. It is not necesssary to insist on the inestimable value of the latter class of school; but it is of the first importance that the public should perceive the distinction referred to by Mr. Hartog, and that they should not think that they are following the example of a country like Switzerland, which eleven years ago was spending over £14,000 a year on the Zürich Polytechnic, when they vote a large sum to one of the many English polytechnics and technical schools, now springing up so rapidly with the help of funds derived from the Customs and Excise duties, while but meagre support is given to the institutions for the training of managers and manufacturers. As Mr. Hartog remarks, the university colleges combine the faculties of a German or Swiss university with those of a *polytechnicum*, but the existence of the technical part of the instruction given is often ignored because it is called university teaching, and not technical instruction, and

because side by side with the teaching of science there is the teaching of the "humanities." The remarks conclude with a statement of the amount allotted from the public funds to university colleges. Out of the sum available under the Local Taxation Act about £600,000 a year is devoted to technical education, but only £23,854 was given to fourteen university colleges in England and Wales in 1892–3 by twenty local authorities, in addition to a sum of £20,550 provided by the Treasury, of which nearly half (£13,300) went to the three Welsh colleges alone. The support certainly seems insufficient for the great services rendered by the colleges to the nation.

The third Report of Mr. J. A. Bennion, the Director of Technical Instruction in the County Palatine of Lancaster, was presented to the County Council a few days ago. It is clear from the report that every effort is being made by the Committee to expend judiciously the funds at their disposal. A sum of £28,500 was distributed among the urban and rural districts of the county last year. The following amounts were voted for work in special subjects:—Navigation, £250; Sea Fisheries, £300; University Extension Lectures, £500; Horology, £250; Mining, £500; Silk Industry, £500; Plumbing and Sanitary Science, £750; Horticulture and Bee-keeping, £500; Practical Agriculture (including Veterinary Science, Poultry-keeping, and allied subjects), £1000. In addition to the ordinary sums allotted to each district, special grants, amounting to nearly £1000, were made for the purpose of purchasing apparatus and appliances. University College, Liverpool, and the Owens College, Manchester, each received a grant of £400 for the same purpose. Classes in horology are held at Prescot, but they are quite inadequate for the whole county; and do not impart the thorough teaching, either theoretical or practical, that is given on the continent. A deputation from the Committee visited some of the Continental Schools of Horology, and as a result of their inspection they strongly recommended the establishment of a County School of Horology, similar to the school at Geneva. It was afterwards resolved at a large and representative conference that "it is desirable to establish a Technical School of Horology and Scientific Instrument-making, including electrical, optical, and mechanical instruments, both practical and theoretical, for the County of Lancaster." Efforts are now being made to put this resolution into effect. The establishment of a school to afford effective teaching in subjects relating to the silk industry is also under consideration. It is proposed to found the school upon the model of the Seidenweb Schule of Wipkingen, in Zurich. For the purpose of providing instruction in practical agriculture, a farm and farm buildings, covering nearly 150 acres, has been acquired at Hulton, near Preston. A vote of £650 was made to the Harris Institute for special courses to agricultural students; and a number of lectures on subjects relating to agriculture were delivered in various parts of the county, while agricultural experiments were carried on in several districts.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 7.—Absorption spectrum of pure water for red and infra-red rays, by E. Aschkinass. The "extinction coefficients" of water for the various wave lengths at the red end of the spectrum were determined by the bolometer, and calculated by the formula

$$J' = Je^{-\epsilon d},$$

where J is the intensity of the incident, and J' that of the transmitted light, d the thickness of the layer in cm, e the basis of the Neperian logarithms, and ϵ the "extinction coefficient," which therefore means the reciprocal of the thickness which a ray must traverse in order to be reduced to $1/e$ of its original intensity. Of these extinction coefficients 200 are given, for wave lengths extending from 0·4500 μ to 8·40 μ. The minimum is at λ = 0·5375, being 0·00005, and the maximum of 2733 is attained at λ = 3·02 μ. A second maximum occurs at 6·00 μ. Between 6·7 and 8·5 the values of the extinction coefficients [illegible] between 700 and 1000.—Absorption of radiant heat by [illegible], by Charles Ironey. The liquids investigated were [illegible] in cells between an iron block and a thermopile. Among the results obtained are the following: Whenever, in a [illegible] compound, H, O, HO, or N are replaced by S or halogens, the transmittance of the solution is [illegible]. In homologous series the transmittance is regularly changed by every addition of CH_2, but the direction of this change depends upon the nature of the other atoms contained in the molecule. The absorptive power of a compound does not essentially depend upon the size of the molecule, but seems to be a property of the constituent atoms. The greatest influence is always due to H, N, and also O. In isomeric compounds the diathermancy is different, and the difference is not only connected with the difference of atomic volume of the elementary atoms, but also with the difference of linkage of the atoms amongst each other; in saturated compounds the diathermancy (transmittance) always increases with the atomic volume. The determination of the diathermancy is the most delicate test available for the purity of organic liquids or salts which are soluble in highly diathermanous liquids.

SOCIETIES AND ACADEMIES.

London.

Royal Horticultural Society, June 25.—Mr. McLachlan in the chair.—Mr. Wilson exhibited a pot containing some seedling plants, in blossom, of the North British species *Primula scotica*, which is found in pastures of Orkney, Caithness, and Sutherland. The flowers are homomorphic, not having the stamens and pistils of different lengths as in most other Primulas.—Mr. Jackman exhibited small trees of *Fagus sylvatica*, with the leaves small, entire, and round. As the trees exhibited an erect form, with short branches, it would seem to be the result of some check to growth, the form of the leaf representing a less developed state than that of the ordinary type of tree. Mr. Colinette, of Guernsey, forwarded some hazel wood found in peat near the coast of Guernsey, containing flint implements, stone rings, and pottery, presumably neolithic. No hazel is now known to be indigenous to Guernsey.—Mr. McLachlan exhibited specimens of *Melanostoma scalare* attached to flowering stems of a grass, *Glyceria fluitans*.

July 23.—Dr. M. T. Masters described a curious case of *Cypripedium* malformed, received from Messrs. Sander and Co., in which the sepals were normal, but the two petals and lip were absent. Dr. Masters also drew attention to a peculiarity in the venation of the lobed leaves of *Lavandula dentata*.—Dr. Ch. B. Plowright forwarded specimens of the parasitical fungus *Aecidium nymphaeoidis*, with the following observations: "This Aecidium has been stated by Chodat to be connected with the Puccinia on *Scirpus lacustris*. In November 1877, *Puccinia scirpi* was found floating in the river Ouse at King's Lynn. During the past winter I found it on the bulrushes (*S. lacustris*) in the 'Old Bedford' at Earith, Huntingdonshire. On revisiting the spot this July the Aecidium on Villarsia was met with in great abundance." Dr. Plowright also sent specimens of the fungus *Aecidium chenopodii*, with some remarks upon them. With reference to the specimens of flies attacked by a fungus, brought before the last meeting by Mr. McLachlan, it was reported from an examination made at Kew that "the fungus is *Empusa conglomerata*, Thaxter (a somewhat rare species), parasitic on Diptera, especially the larvae and imagines of Tipulae. Distrib. Europe and United States. This is the first record for Britain."

MM. Letellier et Fils forwarded from Caen some growing plants of thornless gooseberry, from which they have issued four kinds, raised by M. Ed. Lefort, of Meaux, France. The usual triple spines were either quite absent, or represented by mere rudiments only. Mr. Cannell sent some trusses, with small jagged-edged petals of a crimson colour, approximating the original wild form. They appeared among his long-selected beds of sweet williams, the margins of the petals being rounded and smooth.

Paris.

Academy of Sciences, August 5.—M. Marey in the chair.—Experimental study of the transverse vibrations of cords, by M. A. Cornu. The complex vibrations of strings produced as in actual musical instruments have been studied. The transverse vibrations of a string, excited in any way whatever, are always accompanied by torsional vibrations, the torsional elasticity of the cord taking effect in the same way as the transverse component of the tension. Not only is the actual vibration complicated by these torsional vibrations, but, in many cases, the transverse vibrations are themselves rendered more complex by the fact that strings are seldom or never symmetrical about their axes. The vibrations have been studied by means of very

light mirrors attached preferably to the portion of the string near one of its points of attachment or a node. Light figures similar to Lissajous' figures have been obtained. With the mirror attached parallel to the axis, all the components of the vibration are effective; when its plane is perpendicular to the axis, the torsional vibrations are eliminated.—Some considerations on the construction of great dams, by M. Maurice Levy.—The international committee on glaciers. A note by M. F. A. Forel. From the observed facts it is deduced that the general behaviour of glaciers is individual and special to themselves. There are some traits, however, which appear in certain cases in connection with the whole of the glaciers of a country. The duration of the oscillations of glaciers is measured in years by tens, the mean being at least thirty or forty years. The same variations are met with in other glacier regions as well as in the Alps. The committee ask the co-operation of scientific observers to ascertain whether there is coincidence, alternation, or lack of agreement in glacial variations: (*a*) In the different glaciers of the same continent; (*b*) in the glaciers occurring in the same hemisphere; (*c*) in the glaciers of all parts of the earth.—On the Brownian movement, by M. C. Maltézos. The conclusion is drawn that the Brownian movement is a capillary phenomenon.—Lighting by luminescence, by M. A. Witz. Lighting by means of a vacuum tube in circuit with a Holtz machine or Ruhmkorff coil is proved to give a smaller proportion of heat in relation to the quantity of light developed than any other means of obtaining light, yet the light so obtained requires the expenditure of much more energy per candle-power than ordinary sources, and hence the disposition of apparatus will require to be very much modified before light can be produced commercially at a low temperature.—On the nuclei of the Uredineæ, by MM. G. Poirault and Raciborski.—On diphtheritic anti-toxin, by MM. Guérin and Macé. The active substance appears to be of the same nature as the soluble ferments classed under the name "diastase."—On a toxic substance extracted from the suprarenal capsules, by M. D. Gourfein.—Instantaneous hyperglobulia, by peripheric stimulation; consequences, by M. Jules Chéron. Hypodermic injection of artificial serum or stimulating actions on the sensitive skin surface (such as a cold douche, massage, &c.) cause an immediate loss of the anæmic symptoms in patients suffering from anæmia. The result is probably produced by a stimulation of the central nervous system, followed by a bracing up of the vascular system as evidenced by the increase in arterial pressure. The apparent increase in the numbers of red corpuscles is caused by the greater extravasation of serum brought about under the greater pressure.

NEW ZEALAND.

Philosophical Institute of Canterbury, May 1.—Mr. C. W. Purnell, on "true instincts of animals." The definition of the term "instinct" has been greatly narrowed of late years. Formerly every act of an animal betokening intelligence was ascribed to "instinct," but the term is now restricted to acts which are performed in an apparently mechanical manner by generation after generation, and seem to be prompted by some other faculty than intelligence. The author thought that the definition could be still further restricted. Writers upon the subject had not taken sufficiently into account how much the young animal might be taught by the old, and how much it might learn from imitation. The migratory habits of certain birds, for example, were always set down to instinct, but birds usually migrated in flocks, and, in any case, with the young bird it was "follow my leader." The same remark applied to the periodical migrations of the Norwegian lemming, the salmon, and other animals. The nest-building habits of birds could be similarly explained; and even such extraordinary habits as that of the Australian Megapodidæ, which formed immense mounds of vegetable and other matter, and deposited their eggs in the midst, leaving them to be hatched by the heat evolved from the fermentation of the decaying mass. The beaver's remarkable habit of constructing dams and canals, some of which are of great antiquity, and which, if constructed by human beings, would be deemed proofs of considerable engineering skill, illustrated the author's argument. The young beaver remained in the parental lodge until the summer of its third year, when it began housekeeping for itself, so that it had abundant opportunity, during its youth, of receiving instruction from its elders, in the peculiar ways of beaverdom, and when it did make a start in life upon its own account, it still enjoyed opportunities of receiving instruction and of gaining skill by experience. Cats, dogs, and monkeys instructed and corrected their young; and the adult carnivora taught their offspring how to capture and kill their prey. Some of the most remarkable so-called instincts displayed by animals could be accounted for in the same way, and when we came to analyse these instincts, we found them to be nothing more nor less than racial habits, transmitted from generation to generation, and acquired in a similar way to that in which the racial habits of mankind are acquired. Mr. Purnell then referred to the singular instinct of the huanaco, which, in the southern part of Patagonia, resorted to ancient dying places, whither all individuals inhabiting the surrounding plains repaired at the approach of death. Mr. Hudson, author of "The Naturalist in La Plata," attributes this practice to the possession by the huanaco of "a fixed immutable instinct, a hereditary knowledge, so that the young huanaco, untaught by the adults," goes alone and unerringly to the dying place. Mr. Purnell considered this an unwarranted assumption, and that it was a far more likely supposition that, if a young huanaco was *in extremis*, the older members of the herd expelled it from their ranks, as other sick or wounded animals are usually expelled by their fellows, and indicated to it whither it should go. Traditional and tribal memories, perpetuated by communication from old to young, would account for such habits as the hive-constructing habits of the bee and the domestic and military habits of the various species of ants, which were so commonly regarded as typical of the more wonderful development of instinct in the lower animals. The fact that many so-called instinctive acts were really the products of education and experience, did not clash with the view that animals might be and probably were born into the world with a hereditary predisposition to certain tribal habits which rendered instruction in those habits easier and more effective. The mental, like the bodily, structure of any individual animal was the sum and outcome of all its progenitors' faculties, and just as its bodily organisation was better fitted to perform certain acts than others, so its mental organisation was better fitted for certain mental operations than others. Body and mind were correlated and developed in unison. The web-building spiders secreted web-building material in their bodies, and possessed highly specialised organs enabling them to produce the material in such manner and quantity that it can be used in the construction of snares, and just as this specialised anatomical structure has gradually been evolved from simple beginnings, so the mental faculty required for the construction of snares has been evolved with it. The spider is, so to speak, endowed with mental as well as with anatomical spinnerets. If we eliminated all such habits as might have been acquired from teaching or observation, there were left comparatively few fixed habits of animals which, in the present state of our knowledge, could not be accounted for by the individual having received instruction from its fellows, or gained knowledge from its own observation, and it was to such habits that the author proposed to confine the term "instinct." For the purposes of this paper, he would call them "true instincts." These true instincts were found almost solely amongst insects. By way of illustration, he would take the case of the caterpillar of a butterfly (*Thekla*), which fed within the pomegranate, but when full-grown gnawed its way out, and then proceeded to attach with silk threads the point of the fruit to the branch of the tree, so that the fruit could not fall before the metamorphoses of the insect was complete. Here, there was apparently no means by which the caterpillar could receive instruction, since no visible intercourse took place between the butterfly whose offspring the caterpillar was and the caterpillar. In considering this problem, we must firmly grasp the fact that, although the caterpillar, the pupa, and the imago were, to outward seeming, three distinct animals, in reality they were but varying phases of the same animal. Therefore the insect possessed the power of inheriting memories. We could understand how the memory of an inherited habit useful and common to one phase of the animal's existence, might readily be transmitted from the perfect insect to its offspring through the various stages of that offspring's existence. The order in which these memories were transmitted would be the order in which they would manifest themselves in the new life cycle. Did, then, the Thekla possess the power of transmitting the habit referred to? It appeared not unreasonable to suppose that such a habit might become (metaphorically speaking) so ingrained in the mental constitution of the animal as to be capable of transmission from parent to offspring. The life of an insect was short and monotonous, and its range of locomotion limited; its world was a small world; it enjoyed little scope for

variation of habit, and its ways of life consequently tended to become stereotyped upon its mental system, and so transmitted from generation to generation. As the mental nature of the animal grew more complex, instincts became more rare, because the animal exercised more choice in its actions. The fact that the nervous system of the Invertebrata was materially different from that of the Vertebrata, was full of significance in this connection. Amongst true instincts he would class such acts of protective mimicry as those performed by the Phasmidæ; although their alleged practice of shamming death might possibly be constitutional lethargy, which had misled observers. The fear which young animals, including children, usually manifested towards what was really dangerous to them, might also be classed amongst true instincts; although recent experiments by Prof. Lloyd Morgan proved that the fear was not universal. Mr. Purnell next discussed Spalding's experiments with newly-born chickens, ducks, pigs, &c., which went to show that the young of these animals were capable of performing many acts, apparently intelligent, without instruction. It must be borne in mind that the young fowl, duck, or pig came into the world with its intelligence pretty fully developed, although it grew wiser as it grew older, and all the acts mentioned by Spalding were intelligent acts, not acts performed in an unvarying fashion, but acts varying with surrounding circumstances. He therefore concluded that these acts could not be attributed to instinct, but were directed by intelligence. What he had denominated "true instincts" suggested an analogy with reflex actions, but the analogy was fallacious. Singleness was of the very essence of a reflex action. The action might be complex in its manifestation, but it was essentially one act, of which active consciousness and reflex action were contradictory terms. A true instinct commonly involved a sequence of acts, directed towards a definite end, while the acts were consciously performed.

New South Wales.

Linnean Society, June 26.—Prof. T. W. E. David, Vice-President, in the chair.—(*a*) Notes on the Omeo Blacks; (*b*) on the Monaro Blacks, with a description of some of their stone implements; (*c*) a native burial-place, near Cobbin, Monaro, by R. Helms.—Descriptions of some new *Araneidæ* of New South Wales (No. 5), by W. J. Rainbow. Three new species of orb-weavers of the genus *Nephila* from New England and Sydney were described. The fact was recorded of a young bird (probably *Estrilda temporalis*) having been caught in a web of *N. ventricosa* in the vicinity of Sydney; also that Mr. A. J. Thorpe, of the Australian Museum, had seen an emu wren (*Stipiturus malachurus*) entangled in the web of one of the *Nephila* at Madden's, near Belle Plains (N.S.W.); also at Cape York, several of the blue warblers, notably *Malurus browni* (Vig. et Hors.) and *M. amabilis* (Gould). It was pointed out that it is only young birds and those of weak wing power that are arrested by such webs; and doubt was expressed as to the correctness of the assertion of some writers that birds so caught are devoured by the spiders. The author also pointed out that each web is placed in position by the unerring instincts of the spider, simply because the situation is such as will assure abundance of food in the shape of insects, and that it is merely an accident when a bird becomes entangled in the toil. The paper concluded with a description of the mode of coition in the *Nephila*, and a list of the previously described Australian species of the genus.—On the methods of fertilisation in the *Goodeniaceæ* (part ii.), by Alex. G. Hamilton. Eleven species of *Dampiera* were treated. Of these four are usually cross-fertilised by the aid of insects, but in the remaining seven while cross fertilisation is possible by insect aid, yet self fertilisation must occur more commonly.—On a new fossil mammal allied to *Hypsiprymnus*, but resembling in some points the *Plagiaulacidæ*, by Robert Broom. The remains described under the name of *Burramys parvus* are those of a small marsupial not larger than an ordinary mouse. The form is specially interesting in having but three true molars in each jaw; and a very large grooved premolar with serrate edge very similar to that found in the Eocene genus *Neoplagiaulax*. Its affinities were dealt with at some length, and an endeavour was made to trace its relationship phylogenetically.—On some new or hitherto little-known land shells from New Guinea or adjacent islands, by C. E. Beddome. Three new Papuan species, viz. *Hemiplecta brumeriensis*, *Papuina brumeriensis*, and *Pupina beddomei*, were described, and other known land shells from German New Guinea were discussed.—Plants of New South Wales illustrated. No. viii. *Acacia lanigera*, A. Cunn., by R. T. Baker. This is by no means a rare plant in New South Wales, and yet of the several descriptions that have been published from time to time, not one is sufficient in detail to accurately determine the species; in the specimens described in the Flora Australiensis the pod was incorrectly matched. The author gave the results of an examination of perfect material from many localities, and his paper should prove of assistance in the future in the elucidation of cognate species which at present are not easy of determination.—Description of a new species of *Acacia* from New South Wales, by J. H. Maiden and R. T. Baker.

Gottingen.

Royal Society of Sciences.—The *Nachrichten*, Part 2 for 1895, contains the following memoirs of scientific interest:—

February 9.—W. Voigt: Some applications of the thermodynamic potential. Franz Meyer: On the structure of discriminants and resultants of binary forms (second note).

February 23.—E. Ritter: On the representation of groups of functions by means of one base.

March 9.—J. Orth: On mucous tissue and myxomata, with special reference to the hydatidiform mole.

March 23.—A. von Koenen: On the relation of river-valleys to erosion and to the deposit of diluvial and alluvial formations. O. Mugge: On the plasticity of ice-crystals.

May 11.—O. Wallach: Researches from the University Laboratory of Gottingen. (1) On a method of preparing ketones; (2) on derivatives of piperonal (heliotropin); (3) the oxidation-products of terpinol; (4) the reduction-products of carbon. R. Dedekind: On an extension of the symbol (a, b) in the theory of moduli. E. Netto: On the structure of the resultants of binary forms.

BOOKS, PAMPHLET, and SERIALS RECEIVED.

Books.—Traité de Mécanique Générale: H. Resal, Deux. Edit., Tome 1 and 2 (Paris, Gauthier-Villars).—L'Arithmétique Amusante: E. Lucas (Paris, Gauthier-Villars).—Traité D'Arithmétique: C. A. Laisant et E. Lemoine (Paris, Gauthier-Villars).—Philip's Handy-Volume Atlas of the World: E. G. Ravenstein (Philip).—Philip's Systematic Atlas, School Edition: E. G. Ravenstein (Philip).—A Glossary of Greek Birds: Prof. D. W. Thompson (Oxford, Clarendon Press).—Descriptive Catalogue of the Spiders of Burma preserved in the British Museum: T. Thorell (London).

Pamphlet.—Baby Buds: E. Ethelmer (Congleton, Mrs. W. Elmy).

Serials.—Engineering Magazine, August (Tucker).—Journal of the Anthropological Institute, August (K. Paul).—Strand Magazine, August (Newnes).—Himmel und Erde, August (Berlin, Paetel).—Sitzungsberichte der Physikalisch-Medicinischen Societät in Erlangen, 26 Heft, 1894 (Erlangen).—Journal of the Franklin Institute, August (Philadelphia).—American Journal of Science, August (New Haven).—American Naturalist, August (Philadelphia).

CONTENTS.

THURSDAY, AUGUST 22, 1895.

TWO BOOKS ON ARCTIC TRAVEL.

The Great Frozen Land. By Frederick George Jackson. London: Macmillan and Co., 1895.)

Ice-bound on Kolguev. By Aubyn Trevor-Battye. (London: Archibald Constable and Co., 1895.)

BOTH these books are well worthy the attention of every one interested in Arctic travel. But little was known about the island of Waigatz, and still less of Kolguef. Both books are profusely illustrated, and provided with useful maps, but some of Mr. Jackson's pictures are borrowed without acknowledgment. As might naturally be expected, the Samoyedes occupy the greatest share of attention, but some information respecting the fauna and flora of both islands is added, and the difficulties of travelling are dwelt upon with considerable detail.

The "Great Frozen Land" has been compiled by Mr. Arthur Montefiori from Mr. Jackson's journal of his trip across the tundras of European Russia, from the Kara Gates to the Varanger Fiord *viâ* Ust Zylma and Archangel. In one of the appendices, Mr. Montefiori explains the object, method, and equipment of the Jackson-Harmsworth Polar Expedition, and in another appendix Mr. Joseph Russell Jeaffreson adds some notes on the ornithological results of Mr. Jackson's journey.

The narrative begins on August 25, 1893, outside the lagoon of the Pechora, and ends on January 18, 1894, at Vadsö, the frontier town of Norway. The greater part of the book has been devoted to the Samoyedes, but the real object of the journey was neither ornithological nor anthropological, otherwise it would not have been undertaken in winter. Mr. Jackson, as everybody knows, was planning an expedition to Franz Josef Land, and the very practical idea occurred to him that a winter among the Samoyedes must give him a personal acquaintance with the difficulties of land travelling in the high north, and might suggest a successful way of battling with some of them.

Mr. Jackson must be congratulated upon his editor. Mr. Montefiori has spared no pains to make the book interesting. The information which Mr. Jackson himself procured, especially on the island of Waigatz, is valuable, and it is supplemented by quotations from Rae, Castrén von Strahlenberg, Purchas his Pilgrimes, and the works of various other travellers.

Unfortunately the ornithological part has not fallen into such good hands. There are a dozen or more gross mistakes in the spelling of the names of the birds, and in addition there are some curious inconsistencies. In the preliminary observations we are told that Mr. Jackson brought home "of swans—not Bewick's—but the common variety of that region," in spite of which the only swan in the list (No. 28) is Bewick's swan. Mention is made of grossbills. (Does the writer mean crossbills or grosbeaks?) Of the little stint (No. 45) it is stated that the only authentic eggs were those taken by Middendorff. There is no reason to believe that Middendorff ever found the eggs of the little stint. The eggs which he records as being those of *Tringa minuta* were probably those of *Tringa ruficollis* and possibly those of *Tringa subminuta*. The first identified eggs of the little stint were taken on July 22, 1875, by Mr. Harvie-Brown, on the eastern shores of the lagoon of the Pechora, and a few days later a score had been obtained by the expedition. Other eggs equally authentic have since been taken in Lapland, Novaia Zemblia, and Kolguef. It is extremely unlikely that the identification of the species in the list is always correct. No. 10 doubtless refers to *Phyllosopus tristis*, and not to the chiffchaff: No. 12 is more likely to be a redpole than a siskin; No. 39 is doubtless *Ægialitis hiaticula*, and not *Æ. curonica*, and No. 53 is more likely to be *Stercorarius richardsoni* than *catarractes*. In but few cases is the exact locality given, so that on the whole we must condemn the list as worse than useless.

Mr. Jackson went out on one of Captain Wiggins' numerous voyages to the Yenesei, and was left on the southern shore of the Yugorski Strait, with little or no knowledge of the language of the country, to fight his way as best he could. He was anxious to go to the Yalmal Peninsula, but the Samoyedes declined to take him there. After reading the account of the difficulties which Drs. Finsch and Brehm encountered, it must be admitted that their decision was very wise. Mr. Jackson was, therefore, obliged to content himself with exploring Waigatz Island, and succeeded in making the detour in a fortnight. The north of the island enjoys a milder climate in winter than the south, the Yugorski Straits being frozen over, whilst there is always more or less open water in the Kara Gates.

Winter came upon the adventurous traveller rather suddenly during the second week of October, and on the 13th he began his sledge journey to the Norwegian frontier. During the three months that this occupied, Mr. Jackson lived among the Samoyedes and picked up many useful hints as to dress, food, &c., as well as accustoming himself to camping out in the snow, travelling by sledge, using snow-shoes, &c. This information and experience will doubtless be of great value to him on his expedition to Franz Josef Land. It is worth something to know, instead of only to suspect, that you have pluck to face the difficulties of Arctic travel, and every one wishes a safe return to a traveller who with but small previous experience has gone to try his luck in battling with enormous difficulties.

Mr. Trevor-Battye's book treats of the journey which he made in 1894 to a still less known part of the Arctic Ocean. The island of Kolguef lies about 150 miles to the west-north-west of the lagoon of the Pechora, whilst the island of Waigatz lies about as far to the north-east of that basin. Mr. Trevor-Battye sailed from Scotland in the steam-yacht *Saxon* on June 2, and landed, with his bird-skinner, on the west coast of Kolguef on the 16th; but as ill-luck would have it, they went again on board, and did not finally leave the vessel until the 21st, after the ice had driven them to the north of the island. On August 18, a Russian merchant from the Pechora arrived on Kolguef, and Mr. Trevor-Battye and his companion left in his boat on September 18, and after a nineteen hours somewhat perilous sail, reached the mainland. In two months he was back again in England.

Mr. Trevor-Battye appears to have kept a copious journal, and very interesting reading it is. It bears internal evidence of having been written on the spot by

one who was well trained in habits of observation, and accustomed to the drudgery of making daily notes of what he saw. The remarks on the peculiarities of the Samoyedes are valuable from their originality, and are an important contribution to the ethnology of Siberia in Europe. The value of the ornithological appendix is in strong contrast to that in Mr. Jackson's book; but it must always be remembered that Mr. Trevor-Battye is himself an ornithologist, and travelled at a time of year when the country was full of birds. Mr. Jackson makes no pretension to any knowledge of ornithology, he travelled at a season when birds were very scarce, his mind was occupied with other thoughts, and he had the misfortune to entrust the few skins he brought home to hands as inexperienced as his own.

Mr. Trevor-Battye's account of the way in which the Samoyedes surround the geese when most of them are unable to fly, because they are moulting their quills before migrating to the coasts of Western Europe to winter, is most graphic.

On the south-east coast of Kolguef the sea is shallow, and at low tide there is much sand exposed within the line of the outer barrier of piled-up ice, which lies some three miles out to sea. In this lagoon thousands of geese retire towards the end of July to moult their flight feathers. When they are in this more or less helpless state, the Samoyedes slip down in their boats through the fog and get behind them, and gradually drive them on shore, where a decoy net has been staked out to receive them. Once inside this trap they are slaughtered without mercy to provide food for the winter. The day's bag was 3300 brent geese, 13 bean geese, and 12 white-fronted geese. Fortunately for the two species of grey geese, they moult a little later than the black geese, so that most of them were able to fly. The Samoyedes told our travellers that the bernacle goose nested at the north of the island.

Mr. Trevor-Battye was fortunate enough to obtain eggs both of the grey plover and little stint. Mention is made on page 209 of the capture of two examples of the curlew sandpiper, but curiously enough this bird does not appear in the ornithological appendix.

There is an interesting appendix on the flora of Kolguef. The cloudberry, one of the most delicious of fruits, which is found on the highest summits of the Peak of Derbyshire, and on the Craven Mountains in Yorkshire, was in flower by the second week of June, but the fruit did not ripen before August 25.

Both Kolguef and Waigatz have an island climate, very different from that of continental Siberia; and it might be said of both of them, as is frequently said of Lapland, that they have eight months winter, and four months no summer. The frequent rains are no doubt very favourable to the growth of many species of plants, but they sadly interfere with the pleasures of camp-life. When the north wind brings down fogs from the Arctic ice in June, and snow followed by rain in July, varied with thunder in August, and frosts in September, it requires some enthusiasm for birds or flowers to enjoy the fight with the storms. There are, however, some compensations. If there be little sunshine there is no night, and when the north wind blows the plague of mosquitoes is stayed. HENRY SEEBOHM.

ANOTHER BOOK ON SOCIAL EVOLUTION.

The Evolution of Industry. By Henry Dyer, C.E., M.A., D.Sc., &c. (London: Macmillan and Co., 1895.)

THIS work contains much valuable suggestion, many admirable sentiments, and a selection of choice extracts from the best writers on social philosophy; but it is hardly what one would expect from its title. The idea of evolution is, no doubt, more or less present to the author throughout his work, and some of its main characteristics are referred to and illustrated by the phenomena of industrial progress; but there is a want of system and of logical connection in the treatment of the subject, and an entire absence of the unity of design, forcible reasoning, and original theory which were such prominent features in Mr. Kidd's work.

Dr. Dyer's book is an eclectic one, inasmuch as it adopts from previous writers such ideas and principles as commend themselves to the author. His frequent quotations are often followed by the remark—"there is much truth in this"—and it is sometimes rather difficult to determine what are his own conclusions. It would not be difficult for both individualists and socialists to find support here to their own views; but the general impression made by the volume is, that the author is profoundly dissatisfied with the present state of society, and is inclined to some form of socialism as the only effective remedy.

In the introductory chapter we find many of the objections to socialism very strongly put, though most of these are objections to particular details rather than to essential principles; yet in the same chapter we find statements of fact which answer many of these objections. Thus we are told (p. 21): "Among the co-operators, for instance, we find men managing, with the highest efficiency, concerns of great extent and importance for salaries smaller than those of bank clerks. They find their real salaries in the success of their work, and in the knowledge that it will lead, not simply to individual riches, but to the welfare of the community, and especially of the workers."

After quoting from the late Prof. Cairnes to the effect that no public benefit of any kind arises from the existence of an idle rich class, he adds: "From a scientific point of view, and therefore from a moral point of view, no man or woman, unless physically or mentally disabled, has any right to remain a member of a community unless he or she is labouring in some way or other for the common good. In every organised society, therefore, there can be no rights apart from duties" (p. 37). This principle is thoroughly socialistic, and would lead us very far indeed; but here, as elsewhere, the author seems afraid to carry out his own principles to their logical conclusions. Further on, he tells us that "In some parts of the country as much as between 40 and 50 per cent. of all the deaths that occur are those of children under five years of age, a state of matters which is a disgrace to our civilisation"; and, after quoting some forcible words of Lady Dilke as to much of England's industrial greatness being due to her practically unlimited supply of the cheap labour of her women and girls, he concludes: "It is therefore evident, both from an economic and a moral point of view, that the individualist system of industry, by itself is not sufficient to bring about a stable social

structure." He describes hospitals as institutions "which are founded for the purpose of taking in some of the waste products of our industrial and social system, and for repairing, as far as possible, the injuries which they have suffered"; and he adds: "Such institutions are sometimes pointed out as the glories of our civilisation. They should, on the contrary, be looked upon chiefly as monuments of neglected duties, and the object of all social reformers should not be to extend them, but so to improve social and industrial conditions as to render them almost entirely unnecessary." This will be a new idea to many good people, but it shows that the author is far ahead of the average social reformer.

Again, he points out that the armies and navies of the world afford most instructive lessons in collective action, and that it would be equally possible to have armies of men organised for industrial work, and navies for carrying on such commerce as was essential for supplying the wants of the community; and in his chapter on "Industrial Training," he shows how necessary it has become to supplement the very imperfect means now afforded to apprentices to learn their business by some systematic and well-organised system under local or other authorities.

In the last chapter, on "Industrial Integration," suggestions are made as to the course of future legislation. The author thinks that it will be made increasingly difficult for people to live upon unearned incomes, while the equalisation of opportunities will reduce the rewards of extra ability. How this is to be effected is not made clear; but the author is decidedly of opinion that "the resumption of the ownership of the land by the community is a first essential to equality of opportunity"; concluding with the rather weak remark, that "the methods to be adopted to bring this about will require very careful consideration, and must be comparatively slow in their operation."

After quoting the opinion of the late Mr. Werner Siemens, that the progress of science will lead not to the increase of great factories, but to the return to individual labour, Mr. Dyer adds:—

"The factory system will continue, and no doubt be extended, for the supply of the common necessaries of life, but the applications of electricity and other methods of obtaining motive power will enable large numbers of small industries to be carried on in country districts. This movement will ultimately bring about a society of integrated labour, which will alternate the work of the field with that of the workshop and manufactory. In order that the evils arising from unlimited competition may be avoided, these departments of work will all be so coordinated that a considerable region will, to a large extent, be self-contained as regards its requirements, and will produce and consume its own agricultural and manufactured necessaries of life."

This conclusion has been reached by the present writer and some others, mainly from broad considerations of economy. But when it is set forth in a work which professes to trace and discuss "the evolution of industry," we expect to be shown that it is a logical and inevitable result of the evolution that has occurred and is now going on. This is nowhere done, and in this respect the book must be pronounced a failure, although there is much in it with which every friend of progress and every student of social science must heartily agree.

ALFRED R. WALLACE.

MAYAN HIEROGLYPHICS.

A Primer of Mayan Hieroglyphics. By Daniel G. Brinton. Publication of the University of Pennsylvania Series in Philology, Literature, and Archæology, vol. iii. No. 2. (London: Ginn and Co.)

ALL who are interested in American archæology (and especially those who do not read German) must feel greatly indebted to Dr. Brinton for his "Primer of Mayan Hieroglyphics," for in this little book he has brought together the result of work done during the last few years in America, England, and Germany, and his own extensive knowledge of the subject of which he treats gives the highest value to his selections and his comments.

That there has been a distinct advance made all along the line cannot now be doubted, and material for study has not only increased, but has been made more generally available to the student

Dr. Brinton divides the Maya inscriptions into their three elements—mathematical, pictorial, and graphic, and proceeds to review them in that order. He first describes Prof. Förstemann's interesting investigation into the Maya notation for the higher numbers, and then enumerates the various divisions of time in use amongst the Mayas, and points out that the bringing of these irregular numbers into unison with the lunar and stellar years is the difficult task which lies before the investigator.

"We need not search" [in the inscriptions] "for the facts of history, the names of mighty kings, or the dates of conquests. We shall not find them. Chronometry we shall find, but not chronicles: astronomy with astrological aims; rituals, but no records. Pre-Columbian history will not be reconstructed from them. This will be a disappointment to many; but it is the conclusion toward which tend all the soundest investigations of recent years."

Whilst dwelling upon the elaborate and careful researches of what may be called the astronomical school of investigators, Dr. Brinton does not fail to give an instance of how far they differ from their rivals, by quoting the explanation given of a certain series of figures in the "Codex Cortesianus," which, in agreement with Förstemann, he supposes to represent the position of certain celestial bodies before the summer solstice, whilst Prof. Cyrus Thomas says of them, "It may be safely assumed that these figures refer to the Maya process of making bread"! Such differences of opinion would seem to indicate that the study of the inscriptions has not yet emerged from the stage of guess-work, and to a great extent this is undoubtedly the case; but it is satisfactory to mark how the happy guess-work of the last few years, and the criticism it has provoked, has led to a solid foundation of ascertained fact from which a fresh start can now be made.

Under the heading of "Pictorial Elements," Dr. Brinton gives us a list of the Maya gods and their attributes, gathered chiefly from old Spanish records. Regarding some of those deities, he has already published some interesting studies in "American Hero Myths." He then proceeds to discuss the cosmogony of the Mayas, and in the following pages deals with the pictorial representations of the Maya divinities, referring continually to the list published in 1892 by Dr. Schellhas in the *Zeitschrift für Ethnologie.*

Students appear to be now fairly well agreed about the order in which the glyphs are to be read, and on the identification of the signs representing days, months, and some of the other divisions of time; but there still remains for consideration a large number of glyphs to which the most varied and contradictory interpretations have been given.

The most essential qualification for a student of Maya inscriptions is without doubt a thorough knowledge of the Maya language as it is now spoken in Yucatan. Dr. Brinton, who is a distinguished philologist, has doubtless learnt all that imperfect dictionaries and grammars can teach him, and on that account alone would hold a foremost position in the investigation. But the only way to acquire the special knowledge which is now so much needed is a prolonged residence in Yucatan itself, which can be reached in five days from New York; and it would be good news should we hear that Dr. Brinton has used his great influence in persuading some of the well-endowed universities or colleges in America to establish travelling scholarships for the study of native American languages, and had placed the Maya language first on the list.

OUR BOOK SHELF.

Harrow Butterflies and Moths. Vol. i. By J. L. Bonhote, M.B.O.U., and Hon. N. C. Rothschild, F.E.S., F.Z.S. 8vo. Pp. xi. and 95. Plate. Harrow: Wilbee, 1895.

AT the present day, natural history receives considerable encouragement at our larger public schools and colleges, many of which now boast a Natural History Society of their own, and publish a journal of their own. The naturalists of Harrow School have struck out a bolder path, and have begun to issue a series of manuals of their local fauna, of which this is the second, the first, by Mr. Barrett-Hamilton, having been devoted to the birds of Harrow.

The volume before us includes the *Macro-Lepidoptera* to the end of the *Noctuæ*, and is illustrated by a useful plate presented by the Hon. Walter Rothschild, representing the antennæ of the three British species of *Ino*, the neuration of *Papilio machaon*, and the egg, larva, and pupa of *Vanessa cardui*. The second volume will include the remainder of the *Macro-Lepidoptera*, and the *Pterophoridæ*. South has been followed for Latin names, and Newman for English names, and the indefinite term "variety" has been very properly abandoned.

The district included comprises, roughly speaking, a radius of about five miles from Harrow Hill, and incorporates the notes of a considerable number of observers, the majority being connected with Harrow School. It consists mainly of a record of localities, times of appearance, and habits, with occasional notes on species not found in the district, or on aberrations.

As a record of the present fauna of a restricted locality, this little book will be of permanent value, in view of the changes which are always taking place in the appearance, disappearance, and variation in distribution and abundance of individual species. One or two species which we should hardly have expected to meet with are included in the list, such as *Lycæna corydon*, but we are surprised to miss not only such species as *Aporia cratægi*, which was common round London at the beginning of the century, though probably no Harrow records were kept so far back, but to find no Fritillaries recorded, except *Argynnis selene, euphrosyne, paphia* and *Melitæa aurinia*. The fondness of *Vanessa atalanta* for fruit is noticed; and we may remark that *V. antiopa* also shares this habit with its congener.

Altogether, we have to congratulate the authors and the Harrow School Scientific Society on having produced a very creditable little book, and we hope that it will serve as an incentive to the members of other School Scientific Societies to go and do likewise. W. F. K.

Hand-list of Herbaceous Plants Cultivated in the Royal Gardens, Kew. (Sold at the Royal Gardens, Kew.)

ABOUT a quarter of a century ago, the border-flowers in which our grandsires delighted were all but pushed out of existence by "bedding plants" and ribbon-borders of glaring hue. Nurserymen who had good stocks of the older favourites found them unsaleable, and discarded them accordingly. Then came a change, largely owing to the influence exerted by Mr. Robinson's publications. "Herbaceous" and "Alpine" plants were once more received into favour, and are probably more numerous and more extensively cultivated than ever they were. Kew, as usual, has been responsive to popular demands. In times well within the memory of the present generation, the plants we speak of were grown there, as in other botanic gardens, in ugly gridiron-like beds, an arrangement which might have been suitable for strictly botanical purposes, but which was as unattractive as possible.

To obviate this, and to allow of the plants growing in the most natural way possible, the new rockery was formed, mainly, we believe, after the plans of Mr. Dyer. At any rate, it now forms one of the most attractive features in the garden, and with the frames and "Alpine House," serves excellently to illustrate this class of plants.

A proper catalogue, of course, became necessary, for, unfortunately, the names and descriptions in the most popular books on the subject, are not to be depended upon. The present publication is an alphabetical list, the only information given in addition to the names, being a mention of the botanist responsible for the name, and a general indication of the native country of the plant.

The names of the botanical authorities are given in the contracted form adopted in scientific works; but in a list of this character, which is mainly intended for unscientific readers, the names should either be given in full, or an explanation of the abbreviations supplied.

No fewer than 6000 species, it appears, are now grown at Kew, including, we see, as many as a hundred species of Carex.

A Manual of Book-keeping. By J. Thornton. Pp. 527. (London: Macmillan and Co., 1895.)

THE late Prof. Cayley is quoted by the author to have said of book-keeping, "It is only its extreme simplicity which prevents it being as interesting as it otherwise would be." But what was simplicity to the master of pure mathematics is very far from being so to the average shopkeeper, as witness the testimonies of Official Receivers in Bankruptcy. As Mr. Thornton points out, a general opinion among uneducated tradesmen is that book-keeping was invented to conceal the facts; and therefore they think the least they know about it the higher is their code of commercial ethics. This book will undoubtedly assist in removing such mistaken opinions; it is the clearest exposition of the principles and practice of book-keeping that we have yet seen, and the most original in design. The science and art of the subject are dealt with simply; the matter is arranged in an admirable manner; and by subordinating details to principles, the author has made his book worthy of the attention of all students who wish to acquire a sound and scientific knowledge of book-keeping.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The University of London.

Mr. Thiselton-Dyer now narrows his attack to my suggestion that in voting on the new Charter, members of Convocation should do so "as at a Senatorial election," *i.e.* by voting papers. This seems a very narrow basis for so severe a condemnation.

The reason for this provision was, I presume, that as many members of Convocation are professional men, masters of schools, &c., it is in many cases difficult, if not impossible, for them to come up to London.

The provision applies, I may add, not only to Senatorial, but also to Parliamentary, elections. I cannot see why Mr. Thiselton-Dyer should assume that a vote so taken would "destroy the prospects of academic study in London." That, however, is not an attack on me, but on the Constituency.

High Elms, August 17. John Lubbock.

Plant-Animal Symbiosis.

In Prof. Stewart's collection at the Royal College of Surgeons there is a preparation of a mimosa which protects itself from browsing animals by providing in its great thorns a domicile for a species of vicious, stinging ants. I believe this example of plant-animal symbiosis comes from one of the West Indian Islands, while on the mainland of America the same species of mimosa exists, but suffers greatly from the depredations of animals, because there is no suitable ant to come and ward them off. If my recollection of the distribution is correct, the following note of a similar phenomenon in South Africa, I think, is of considerable interest.

In a recent tour through the Karroo, in search of the skeleton of the Dicynodons, I came across a mimosa tree which here forms the chief fuel, on one of the lower branches of which there were some very large thorns; one of these had a little oval hole bored just beneath the summit. On breaking it open, there issued an incredible number of ants, considering that they were packed in the space of a pair of spines about four inches long and half an inch in diameter. The asexual forms were of the usual two kinds: the soldiers were about a quarter of an inch long, brown, and very attenuated, showing very markedly the influence of surroundings on form; while the workers were scarcely half the size of their protectors, and of a darker hue. The sexual forms I did not see. The ants emerged from the crack in a very sleepy manner, and did not seem at all aggressive; this may have been on account of the cold, which would affect them more than their relatives which live in the earth. Embedded in the soft wood of the stem, where the two spines meet, were several aphides, which thus were able to feed themselves on the sap of the tree, and yet always be within the house of their owners. In the West Indian thorn-tree the leaves offer a further inducement to the ants to remain constantly near them, by providing at the extremity of the leaflets little masses of a nutritious substance adapted to the digestions of their guests; in the South African tree there is a mass situate at the base of the leaves, similar to that in the cherry, which probably serves the same object. On returning shortly afterwards, I found the ants had trekked with all their cattle, and I failed to trace their whereabouts. The locality was the gold-fields of Spreeunfontein, in the Prince Albert district. Ernest H. L. Schwarz.

Cape Town, August 1.

Definitions of Instinct.

I have read with interest the abstract of Mr. C. W. Purnell's paper which you published in last week's Nature (p. 383). I think he is in error in supposing that young birds do not afford us examples of truly instinctive activities. The way in which a young moorhen swims with accurate coordination, before the down is well dry after hatching, and before it can walk steadily, is very instinctive. I would suggest to Mr. Purnell that there is a wide field for observation open to him among his native birds. If he will hatch some of them out in the incubator, and carefully note what they can do prior to experience, and how their activities are modified by experience, he will help to solve some of the difficult problems of habit and instinct.

I have myself advocated a restriction in the meaning of the term somewhat similar to that for which he argues. I shall be obliged if you can find space for the provisional scheme of terminology thus suggested in *Natural Science* for May 1895, which I have since somewhat extended and amended. To bring it into line with modern biological thought, a good deal of stress is laid on the question of heredity, and on the distinction between the definiteness which is congenital and that which is acquired. It may be premised:

(1) That the terms *congenital* and *acquired* are to be regarded as mutually exclusive. What is congenital in its definiteness is, as prior to individual experience, not acquired; the definiteness that is acquired is, as the result of individual experience, not congenital;

(2) That these terms apply to the individual. Whether what is acquired by one individual may become congenital through inheritance in another individual, is a question of fact which is not to be settled by implications of terminology;

(3) That the term *acquired* does not exclude an inherited potentiality of acquisition under the appropriate conditions. Such inherited potentiality may be termed *innate*. What is acquired is a definite specialisation of an indefinite innate potentiality;

(4) That what is congenital and innate is *inherent* in the germ-plasm of the fertilised ovum.

Congenital movements and activities: those the definite performance of which is antecedent to individual experience. They may be performed either (1) at or very shortly after birth (*connate*), or (2) when the organism has undergone further development (*deferred*).

Congenital automatism: the congenital physiological basis of those movements or activities the definite performance of which is antecedent to individual experience.

Physiological rhythms: congenital (and connate) rhythmic movements essential to the continuance of organic life.

Reflex movements: congenital, adaptive, and coordinated responses of limbs or parts of the body: directly evoked by stimuli.

Random movements: congenital, more or less definite, but not specially adaptive movements of limbs or parts of the body; either centrally initiated or directly evoked by stimuli.

Instinctive activities: congenital, adaptive, and coordinated activities of relative complexity, and involving the welfare of the organism as a whole; specific in character, but subject to variation analogous to that found in organic structures; similarly performed by all the members of the same more or less restricted group, in adaptation to special circumstances frequently recurring or essential to the continuance of the race; often periodic in development and serial in character.

Imitative movements and activities: due to individual imitation of similar movements or activities performed by others.

Impulse (*Trieb*): the affective or emotional condition, whether congenital or acquired, under the influence of which a conscious organism is prompted to movement or activity, without reference to a conceived end or ideal.

Instinct: the congenital psychological impulse concerned in instinctive activities.

Control: the conscious inhibition or augmentation of movement or activity. While the power of control is innate, its special mode of application is the result of experience, and therefore acquired.

Intelligent activities: those due to individual control or guidance in the light of experience through association (voluntary).

Motive: the affective or emotional condition under the influence of which a rational being is guided in the performance of deliberate acts.

Deliberate acts: those performed in distinct reference to a conceived end or ideal (volitional).

Habits: organised groups of activities, stereotyped by repetition, and characteristic of a conscious organism at any particular stage of its existence.

Acquired movements, activities, and acts: those the definite performance of which is the result of individual experience. Any modifications of congenital activities which result from experience are, so far, acquired.

Acquired automatism: the individually modified physiological basis of the performance of those acquired movements or activities which have been stereotyped by repetition.

C. Lloyd Morgan.

A Scheme of Colour Standards.

THE confusion which has long prevailed, and does not promise any immediate disappearance, in the use of colour names, is an inevitable consequence of the absence of any definite standards of colour. In music and form we have well-established and very satisfactory terms to describe definite sense perceptions, and it would be difficult to conceive how we could dispense with them: but for colour perceptions we have neither any well-defined concepts for those terms which have become well established, nor any definite and well-arranged system of colour terms for common use. Those terms which have acquired a somewhat definite significance are nevertheless used for a very wide range of variation. Vermilion and ultramarine, terms which have been used by many of our best authorities on colour, for want of anything better, as a basis for comparison and analysis, are nevertheless used for very variable concepts. The difference between a Chinese and a German vermilion in pigments is very noticeable. A Winsor and Newton "chrome yellow" and a German "chrome yellow" differ by more than twenty-five per cent. of yellow. Among several samples of blue pigments a still greater variation is generally found. When this is true of such terms, what shall we expect will be the case with that very much larger group of terms whose meaning has never reached any considerable degree of accuracy, as olive, citrine, russet, &c., or that still more vague but innumerable class of terms in vogue in popular usage, like "crushed strawberry," "baby blue," "ashes of roses," "peacock blue," "hussar blue," and a host of others still more vague and transitory?

Naturalists have been at very great inconvenience because of the lack of any agreement in the use of colour terms for botanical, entomological, and ornithological descriptions. Our greatest American authority in descriptive botany is sometimes confusing in his description of flowers because of this lack of any standard terms with admitted significance. Zoologists, too, have sought in vain for some basis of agreement, and the futile attempts to establish some such basis of agreement are familiar to every ornithologist.

In applied science and the arts the inconvenience has, if possible, been still greater, inasmuch as the number of persons interested is larger. And this inconvenience is steadily increasing as the revelations of chemistry disclose hues more and more brilliant, for which new names are as constantly coined. With the rapid advance of the art of dyeing the necessity of some system of colour nomenclature becomes more and more imperative.

The valuable research of Prof. Rood has contributed greatly to our knowledge of colour, and that in a time when much less was known on the subject than now. The later contributions of Abney and Church in England have also given valuable additions to the science of colour. The able works of Chevreul, Koenig, and Von Bezold are also important contributions to the subject. Above all, the masterly works of Helmholtz, Hering, Kuhne, and Carpentier are most valuable contributions upon this subject.

But while these have given the greatest help to our understanding of the nature and relations of colour, none of them has given any solution to the problems just now hinted at. No system of colour nomenclature has been offered, nor any set of colour standards proposed.

It was in view of these difficulties that the writer proposed, about twelve years since, while connected with the Springfield, Massachusetts, High School, as teacher of physics, botany, and zoology, that a series of colour standards, based on the hues of the solar spectrum, and selected by a consensus of colour experts, should be adopted as a foundation of all our colour work, and especially that its use in all educational work be made the means of establishing a better and more accurate knowledge of colour. This proposition was received with favour from the first by those to whom it was mentioned, and an attempt was soon made to put the scheme into material form; but the difficulties which lay in the way of producing any pigmentary hues which could in any adequate degree represent the hues of the solar spectrum were so great, that very little progress was made for several years.

The wave theory of light long ago established the fact that vibrations of an almost infinite variety of wave-length in the luminiferous ether impinge upon the human retina and produce the effect which we call white light. From these we may select any wave length we please, and giving it a name, have a colour as accurately fixed as any musical note or geometrical form. The desirability of such a definiteness in the terms which describe colour, all will immediately recognise. It is not necessary that a large number of thus accurately fixed colours should be made the basis of colour nomenclature, for then the eye could not distinguish between the colours selected. Every eye can, however, unless it be colour-blind, distinguish six well-marked colours in the solar spectrum, for which there are well-recognised names. The theory of three primary colours from which all the other hues of the spectrum are derived is no longer possible with the present knowledge of the laws of light, and the always questionable indigo of the rainbow is no longer recognised as one of the distinct spectrum colours. As a matter of practical convenience we may select any number of colours which is found to be desirable for standards if only they are accurately defined. This has been done for the six commonly recognised spectrum colours, red, orange, yellow, green, blue, and violet.

To obtain the agreement of six or eight persons well skilled in the use of colours as to exactly what portion of a projected spectrum of eight or ten feet long should be selected for each standard was a much less difficult task than would first have been supposed. It was found that very great unanimity of judgment prevailed when the comparison was made. The portion of the spectrum having been selected for each colour, two other things yet remained to be done. These were very important factors of the proposed scheme.

First of all the exact location of the area must be determined by careful measurement of the wave-length of its centre. This would make it possible to ascertain or relocate the standard in any part of the world without any material representation of the colour designated: in other words, this makes possible the use of the designated colour as one of a series of universal standards. To render any set of standards of most permanent and wide value, it is desirable that it be adopted by somebody whose authority will be generally recognised. In the case of standards of measurement, the Government establishes standards in the interests of commerce and equity. In most other cases some learned society adopts the standard, and thus gives it the benefit of its own authority. The American Metrological Society has appointed a committee with instructions to report a recommendation for the establishment of six standard colours. The endorsement of such a society would go far toward the establishment of any scheme of colour nomenclature if the scheme be a practical one. Without the element of practicability no authority could make such a scheme of any value.

After several years of careful study of the practical problems involved, especially the relations of the colour standards to one another, it was found that to select any particular pigment as one of the standards, and make the scheme adapt itself to this as a standard, was not only unscientific but unpracticable. The standards if selected with a view to practical or artistic purposes, and most of all with the hope of making the scheme of educational value, must bear a relation to one another not unlike those of the musical scale. It must be possible at least that the union of these standards should produce the intermediate hues of the solar spectrum in colour if not in purity. After much care six standards were selected and at once put to practical use. This was as early as 1884. The exact measurements of the wave-lengths of these standards were published in *Science* for June 9, 1893. The values there given were as follows: Red 6587, orange 6085, yellow 5793, green 5164, blue 4695, violet 4210, in ten-millionths of a millimetre.

These measurements are for the centre of an area of the solar spectrum represented by fifty of the same units. A measurement differing from either of these by twenty or twenty-five would hardly vary to a degree to be perceptible to the trained eye, much less to the ordinary eye. There is, however, a very great variation in different parts of the spectrum. In the orange, yellow, and green, where the change is rather rapid, a small difference is very readily perceived, while in the red as well as in the blue and violet the same difference would be scarcely noticeable.

To Mr. Milton Bradley, of Springfield, Massachusetts, is due great credit for first undertaking to put this idea of spectrum standards into practical working material. When the idea was first proposed he was largely engaged in the manufacture of coloured papers for educational purposes, and he at once undertook to reproduce the spectrum colours in his educational papers. The task proved no easy one, notwithstanding the great advance which the discovery of the aniline dyes had made in the production of brilliant colours. It was only with the utmost persistency that Mr. Bradley was able to accomplish the task which he had voluntarily undertaken. After long and repeated experi-

ments he succeeded in getting coloured papers which are very good reproductions of the hues of the solar spectrum. These papers have now been used for several years very extensively in kindergarten and primary school work, and they are an important means toward the education of a new generation of students to a true conception of colour, a more careful use of colour terms, and a sharper discernment of colour perceptions.

At a meeting of the Society of American Naturalists, held in Boston, December 31, 1890, I read a paper in which was given a more elaborate carrying out of the scheme which I had previously proposed.

In order that any fixed scheme of colour nomenclature may be of some practical value it must, of course, be readily understood by people of only ordinary intelligence, and must be complete enough to meet the ordinary wants of everyday life. There must be something that is so completely fixed as to be perfectly trustworthy for present and future needs.

In the solar spectrum we have an invariable source from which to derive our spectrum standards, and upon these the whole scheme is to be based.

Since, however, the six spectrum standards do not give a very extensive *répertoire* for common use, to say nothing of the needs of the more artistic, it was proposed to introduce between each two spectrum standards two intermediate hues to be formed by the union of the two spectrum standards in definite proportions. Thus between orange and red would be introduced an orange-red and a red orange. In the former red would predominate, while in the latter orange would be more prominent. Inasmuch as these hues are only intended to be combinations of the spectrum standards, it is not necessary, or even perhaps desirable, that these hues be absolutely fixed. If, however, this is desirable in any particular case, it can be accomplished in a manner which will be indicated subsequently. In addition to the two hues introduced between each two standards it is also necessary to use a violet-red and a red-violet (or two purples, a reddish purple and a violet purple) to represent the actual combinations which occur in nature.

It is also very desirable that the standards be produced in some material form in order that it be of any practical value. The task of reproducing the brilliant hues of the solar spectrum in pigmentary material or in glass is much more difficult than one not acquainted with the matter would suspect. It would not be difficult to select well-known pigments, and then determine the wave-length which most nearly corresponds to the hue of the pigment; but any number of such selections would not form a symmetrical series of colour standards. The colours for such a scheme being selected and their wave-length determined, the other and more difficult problem is that of finding some combination of pigment which will reproduce it. This task of reproducing the spectrum hues was a very difficult one. It is impossible to reproduce some of the spectrum colours with the ordinary pigments either in hue or in quality.

Almost at the very outset of this work in colour it was found that it would be necessary to depend upon the somewhat fugitive aniline colours for some of the standards as the only colour material which would approach the spectrum hues in brilliancy. The difficulty of keeping the standards up to tone, so to say, while using somewhat changeable material, is a serious inconvenience but not an insuperable barrier. With the solar spectrum recognised as the source to which we must always go to correct our standards, the great difficulties of colour-study are met. The most desirable thing now to be accomplished is the discovery of some permanent colour material in which to reproduce the spectrum standards. Some convenient form of tablet would then be produced which could be supplied to all who are willing to provide themselves with it, and to these all questions of colour would be referred. The standards thus established, the intermediate spectrum hues are determined by them.

Now, by the use of the Maxwell discs in the standard colours described above, we may fix upon definite proportions of each which we will use for any other hue. If, for example, we desire to introduce between red and orange two hues, we must first of all know something of the relative effect of the two colours, and combine them in inverse proportion to what we are accustomed to call the value of the colours. The colour which has the lowest value will require to be used in larger proportion than the other. In this case we may take a red and an orange disc and put them together in the manner above described. For convenience of measurement, a disc just a little larger than the coloured discs, with the margin graduated into one hundred degrees, is placed behind the coloured discs, and the sectors adjusted as desired. As the red has the lowest value, more of the red disc must be exposed in order to produce an effect equal to that produced by the orange. If it is desired, therefore, to introduce two hues between red and orange, we must still more increase the proportion of red in the combination which we wish to be most like the red. For our orange-red we may use 70 per cent. of red and 30 per cent. of orange, and for our red-orange 59 per cent. of red and 41 per cent. of orange. By making a scale of values for the six standard hues, we may combine them in the manner we have just illustrated and form two hues between each of the standards, and two more by combining red and violet. These twelve hues, with the six standards, give a sufficiently large variety of hues for practical purposes.

For purposes of colour education, however, it must be borne in mind that pure spectrum colours are not often seen either in nature or art. And while it is very important that the student should be taught the spectrum colours at the outset of his education in order to establish some accurate knowledge, derived from the only source of accuracy, the solar spectrum, it is also important that he should become familiar with the effect produced by the mingling of these spectrum hues with the light reflected from other objects, as well as the effect of shadow upon the colours themselves. The mingling of white light with any colour produces a tint of that colour. The tints are what we most often see in all except the most brilliant colours of flowers, not generally of the standards but the intermediate hues. On the other hand, when a coloured object is seen in shadow, or, what is more common, when the coloured surface is so irregular as to reflect here colour and there give no reflection, the effect is to produce a shade of the colour. In foliage the prevalence of shades is the rule, whether we consider the individual leaves or the masses of foliage. A knowledge of these effects is best acquired by the use of a very few tints and shades of each hue. Any convenient number of tints and shades can of course be designated, but a few will serve all the purposes of ordinary educational work. In their educational papers the Milton Bradley Company use the six spectrum standards, twelve intermediate hues, including the combinations of red and violet, two tints and two shades of each of the pure colours, thus giving in all a range of ninety different modifications of colour. With these are used black and white, together with a variety of greys. The facility with which young children learn to distinguish and designate colour is really quite surprising.

But a still larger proportion of the colour effects of nature and art than those produced from either tints or shades are the result of both light and shadow combined with colour. This effect has been well enough described by the term "broken colour." In order to acquire familiarity with this effect, it is desirable to use a series of broken standards, if not also of the twelve intermediate hues. These should be made, as should also the tints and shades, by using proportions which take into account the value of the colours, and, above all, the proportions of white and black used should be such as to avoid destroying the characteristic effect of the colours. Each of these broken standards may have its tints and shades like the standards themselves by increasing the amount of white or black which is combined with the colour.

But perhaps the most interesting point in connection with the introduction of definite colour standards will be the possibility of talking about colour in a definite language. Without such standards this has been impossible. By the use of the Maxwell discs made in the standard colours we may easily determine the composition of any colour. This is a great convenience in the description of colours, for it renders it possible when it is necessary to give an exact meaning to any colour term. Only with standards which can be accurately fixed is this possible. The use of such terms as vermilion, emerald green, ultramarine, chrome yellow, and similar terms as a basis of colour analysis is exceedingly impracticable, since even these terms, although by far the most definite terms in common use, are quite too variable to give results which can be of any real value. For the sake of convenience, the first letter of each colour is used as the symbol of the colour in all formulæ in which the analysis or composition of colour is expressed. N is used for black, to avoid the repetition of B which is used for blue.

The following formulæ will illustrate the practical application of the idea and the value of the spectrum standards in determining the composition of colours. They will also be of interest as

showing the simplicity of the proposed nomenclature and method of expressing the results of analysis.

The first series illustrates the variability of the pigments used by artists. These analyses are made by Mr. Bradley.

A Winsor and Newton "cinnabar green" gives—Y 14, G 11½, N 74½.

A German pigment of the same name gives—Y 12½, G 11, W 2, N 74½.

A Winsor and Newton "light red" gives—O 24, N 76.

A German pigment of the same name gives—O 18, N 82.

A Winsor and Newton "chrome yellow" gives—O 29, Y 71.

A German pigment of the same name gives—O 35, Y 45, N 20.

A Chinese vermilion gives—R 77, O 23.

A yellow ochre gives—O 24, Y 24, N 52.

An Indian red gives—R 7½, O 17½, N 75.

An emerald green gives—G 63, B 14½, N 22½.

One called "chrome green" No. 2 gives—G 16½, Y 55, N 78½.

The following series illustrates the significance of the terms used in describing the colours of dress goods. A very wide range of tints and shades of the colour which is the basis of each term will often be designated by the same name.

A sample of goods called "écru" is—O 11, Y 13, W 18, N 58.

Another sample marked "raisin" gives—R 18, Y 14, W 5, N 63.

A sample called "ashes of roses" gives—R 8, Y 4, W 14, N 74.

The popular colour called "eminence" gives—R 14, Y 19, N 67.

Another popular colour called "emerald" is—G 21, B 3, N 76.

A sample called "crushed strawberry" gives—R 55, O 5, W 27, N 11.

One having the poetic name "absinthe" gives—Y 35, G 45½, N 19½.

Another called "Marion" gives—R 4, O 3, N 93.

A specimen of "hussar blue" gives this—G 4, B 15, N 81.

A sample called "oasis" gives the formula—Y 7, G 10½, W 8½, N 74.

Another called "dove colour" gives—B 9, W 9, N 82.

Still another, called "prairie," gives—Y 10½, G 14½, N 75.

A colour called "Styx" has this formula—R 9½, W 21½, N 69.

A sample of "peacock blue" gives this—G 4½, B 8½, N 87.

A brown, called "vidette," gives this—O 4½, Y 3, N 92½.

A sample of "navy blue" gives—B 6, N 94.

Another of "Turkey red" gives—R 98, O 2.

A rather dark "plum colour" gives—R 3, Y 4, N 93.

A few analyses of flowers will be of interest to others beside the botanist.

The Fringed Polygala (*P. paucifolia*) is—R 48, Y 52.

The Wistaria (*W. frutescens*) gives—for the wings R 11, Y 89; and for the standard R 9, Y 79, W 12.

The Flowering Quince (*Cydonia japonica*) gives—R 95, Y 2, W 3.

The wild Cranesbill (*Geraneum maculatum*) gives—R 28, V 66, W 6.

The Fosythia (*F. viridissima*) is pure spectrum yellow.

The variations of foliage are worthy of note, and a few examples of analyses of the colour of various leaves will perhaps be of interest.

It is possible that some knowledge of these variations on the part of more of our artists might save us some of the abominable greens which so often appear in paintings, otherwise of an excellent grade.

Leaves of the White Oak give—Y 7½, G 11½, N 81.
,, ,, Apple are—Y 5, G 13, W 2, N 80.
,, ,, Copper Beech give—R 17, Y 2, N 81.
,, ,, Hemlock Spruce—Y 2, G 9, N 89.
,, ,, White Pine give—Y 2½, G 11, N 86½.
,, ,, White Birch give—Y 5½, G 11½, W 1, N 82.
,, ,, Hornbeam—Y 5½, G 12½, N 82.
,, ,, Shagbark Hickory—Y 4½, G 9½, N 86.

With discs made in the spectrum standards colour can thus be analysed and the results, expressed as in the examples just given, can be utilised by any number of persons to determine the particular colour about which a statement is made. As these discs are not expensive, and the means of rotating them very simple, they ought to come into very general use. It is only necessary that they be rotated with sufficient rapidity to cause the colours to blend smoothly. For the purposes of studying the harmony and contrast of colour it is desirable to have discs of several sizes, so that two or three combinations of colour may be made upon the colour-wheel at the same time and compared.

Among the practical applications of such a scheme of spectrum standards as that outlined in the preceding paragraphs, some of the most obvious are the only ones which need be mentioned in this connection.

A firm dealing in large quantities of coloured material desires to order a stock in a particular colour which they have not used, and of which they have therefore no samples. By the old method they must find something as nearly like what is desired as possible, and then dictate as best they can just what variations are to be made. Now they can produce the colour with the discs and send the formula only to their manufacturer, who also has a set of the discs, and he "sets up the colour" and then reproduces it in the material desired. The gain is great in several ways. In the first place it saves the dealer much costly experiment to determine just what he really wants. Again, if he is in doubt as to just what a customer wants, he takes him to his colour wheel and ascertains what the desired colour is, and then communicates it to the manufacturer. The architect may spend much time and effort to have his carefully-planned and beautiful villa painted in colours which will be at once in keeping with the style of architecture and the surroundings of the building; but unless he confine himself to colours ready prepared and of certain composition, he is liable to extreme disappointment. A similar use of the colour wheel with standard discs would greatly reduce his difficulties. The artist who accustoms himself to the analysis of colour effects will soon find that he is able to write estimated formulæ which will be of service to him in the subsequent composition of his observations. Above all, the child who is thoroughly educated in any scheme of colours which has a definite basis, and consists of a well-selected series of standards, is starting with a most valuable groundwork for future knowledge and practice. Hence it is that the introduction of systematic colour work into the kindergarten and primary school has so much of encouragement to those who desire a reformation in the use of the terms which describe colour perceptions. Why may we not hope for the time when a system of colour terms with something of the same definiteness as those used in music shall be in common use? Surely there is need of this, and the time is not far distant when this need will so assert itself as to bring about a revolution in our methods of colour education.

Malden, Mass., U.S.A. J. H. PILLSBURY.

Globular Lightning.

ON June 21, about 6 p.m., Dr. Wallis, Mr. Taylor and myself were in our drawing-room on the ground floor, taking shelter from a passing storm; they were seated, and I stood five paces from them. The doors were all closed against the storm, and I went out and, for cool air, opened one. On returning, I saw a globular light, about the size of the full moon, in the air between Wallis and Taylor, and almost instantly I heard in the room a terrific clap of thunder like a cannon. I suffered afterwards from acute pain down the left side of my face. Taylor, who had an iron-headed golf stick in his hand, felt a twinge up his right arm, and a sensation as of singeing in his hair. Wallis felt nothing at all. We all experienced a sulphurous smell. In the adjoining room, leaning against one corner, were two Martini-Henry rifles in leather cases. One was untouched. The stock of the other was almost shattered, splinters lying about the room. The leather covering of the splintered rifle was torn, but the metal part of the rifle quite unhurt. At the point of the wall where the muzzle of the shattered rifle touched the wall, there was a hole 5 × 2½ and 1½ to 2 inches deep. The wall is of mud and plaster. In the room above were two holes in one wall; that is, the wall above that in which the hole appeared below. These holes were smaller than the one below. Just below the two holes stood a wooden case, iron-bound, and at its foot the matting was torn up, but the floor and the case were untouched. In the second room above, that is, the room over that in which I had seen the globular lightning, the wall near the ceiling was cracked for six or eight feet. This was all the damage done that we could find. G. M. RYAN.

Karachi, July 18.

[The above letter was received from Mr. F. C. Constable, who saw the damage described.—ED. NATURE.]

RECENT STUDIES ON DIPHTHERIA.

It is an acknowledged fact that as regards diphtheria, personal predisposition on the part of its victims plays a most important part.

We find this well illustrated by statistics which show that it is in early childhood that the majority of cases occur, and the heaviest diphtheria death-rate is recorded. Thus Feer in Basel found that the most susceptible age to diphtheria lies between the years 2 and 5 and 5 and 10; but that whilst the mortality amongst children attacked in the *earlier* period was 25·4 per cent., in the *later* period, with practically no diminution in the number of cases, the diphtheria death-rate fell to 7·6 per cent. After this period there is not only a great decline in the number of cases of diphtheria, but also a marked decrease in the percentage of deaths, suggesting that with increasing age the human system is enabled gradually to develop means of protection from this terrible disease.

That some such protective power must also be possessed to a large extent by children, follows from the fact that with a disease practically endemic in some of our large cities, so many children succeed in escaping from its ravages, for it is impossible to conceive that all those who have remained unscathed have never been exposed to infection from diphtheria.

Thus Flügge has worked out an interesting diphtheria-table for the city of Breslau during the years 1886–1890, in which he not only confirms Feer's observations upon the connection between age and the diphtheria death-rate, but he also shows very clearly that even in the most susceptible period of child-life, the number of cases of diphtheria is relatively small when compared with the number of children of the same age who are not attacked.

In what does this protective power against diphtheria infection possessed by many children and a large number of adults consist? This interesting and important question Dr. Wassermann has recently endeavoured to answer by making a very extensive examination of the properties possessed by the blood serum derived from patients not suffering from diphtheria, but admitted on other grounds to the Berlin Institute for Infectious Diseases. Careful inquiries were, moreover, in every case made as to the patient's previous history as regards diphtheria, and only those were included in the investigation who had never had diphtheria.

The serum which was obtained from these strangers to diphtheria was in every case tested for its immunising or protective power by inoculating it along with a recognised lethal dose of diphtheria toxin into guinea-pigs, the latter by itself having been proved capable of killing these animals without exception in from 30 to 48 hours.

The results obtained were extremely interesting. Out of seventeen children varying in age from 1½ to 11 years, eleven yielded serum with highly protective properties as regards diphtheria, for all the animals treated with their serum and virulent diphtheria toxin experienced no ill-effects whatever. Two out of the seventeen children yielded serum possessed of slightly protective power, it being found capable of delaying the death of the infected animals, whilst the serum derived from the four remaining children had no protective properties whatever.

Amongst the adults the number of those yielding an anti-toxic serum was much greater, for out of thirty-four individuals the serum of as many as twenty-eight was found to be endowed with protective properties against diphtheria infection; and, as far as the investigation went, it appeared that the possession of such serum, as well as its strength or degree of efficiency, was more marked with increasing age.

That people who have gone through the ordeal of diphtheria possess such antitoxic serum in their system has been shown by various investigators, but, so far as we know, Wassermann is the first who has proved that anti-diphtheritic serum may also be possessed by individuals who have had no previous experience of diphtheria.

This discovery serves to explain how virulent diphtheria bacilli may be present in the throat of perfectly healthy people, without producing any bad results at all. That such may be the case has been proved by most careful and trustworthy observers, and that their presence does not engender diphtheria, we must now regard as probably due to the possession of anti-diphtheritic serum by the individual who so unconsciously has harboured them. Such may also be, and probably is, the explanation of the harmless presence of virulent diphtheria bacilli in the throats of patients convalescent from diphtheria long after the disappearance of all the typical symptoms.

It does not follow, however, that because at some given time a particular individual has been found the happy possessor of anti-toxic serum he may, therefore, rashly assume that he is for ever after proof against diphtheria infection.

It must be remembered that such serum is possessed in very different degrees of strength by different individuals, and may vary also, in one and the same individual, in its protective character at different times.

Research has shown that people possessing only feebly antitoxic serum can contract diphtheria, but in the majority of such cases it is satisfactory to learn that the symptoms are light, and the disease is mastered without much difficulty.

So far as our present knowledge goes, it would appear reasonable to admit that although the possession or non-possession of antitoxic serum of varying degrees of strength may not be the only circumstance which regulates the fluctuating personal disposition towards diphtheria infection, that yet it may be regarded as an important factor, and Wassermann considers principal cause, in determining the apparent idiosyncracies of diphtheria infection. What the mechanism may be whereby this anti-toxic serum is produced in the system is still a mystery; that it should be possessed by infants only eighteen months old, would incline to the belief that it is natural or inborn, and not subject to later processes of evolution.

On the other hand, however, we have the well-established fact that the serum of animals which have a natural or race immunity to a particular disease, is wholly devoid of power to confer protection from this disease on other classes of animals.

This remarkable circumstance has been once more very clearly demonstrated by Wassermann in the case of diphtheria, to which disease white rats are absolutely immune. In order to test the character of white-rat-serum as regards diphtheria infection, fatal doses of diphtheria toxin were administered to guinea-pigs along with such serum, but in no single case did the latter survive, showing that this serum possessed no anti-diphtheritic properties whatever, and was incapable of protecting animals from diphtheria infection.

Thus, on the one hand, we find that natural or race immunity to a particular disease does not provide protective serum against infection from that disease in other animals, and, on the other hand, that the serum of individuals who have never had diphtheria, does provide in many cases such protective serum.

Now Wassermann argues from these facts that the possession of protective human serum is not natural or born with the individual; for otherwise, as in the case of white-rat-serum, it would be incapable of conferring immunity, that it must therefore rather be regarded as a later acquisition, and subject to evolution processes.

In pursuing this line of reasoning, Wassermann assumes that race immunity found to be characteristic of a particular description of animal is necessarily of the same character as exceptional immunity confined to particular

individuals of a race. In the one case it belongs to the whole race, whilst in the other it is possessed by only particularly fortunate individuals of a race.

Does not this point rather to the operation of exceptional circumstances, in which, possibly, heredity may play a part? How is it that whereas some families appear to have a faculty for contracting every zymotic disease, others exposed to similar conditions, have an equally characteristic faculty for escaping such diseases?

The impression is irresistible that such a faculty is born with or natural to the individual.

It may be argued that the white-rat-race-immunity may also be ascribed to the operation of heredity. This is quite possible, but in the one case the immunity is perfected or heredity has accomplished its work, whilst in the other it is incomplete and is still in an evolutionary stage. The race immunity to diphtheria, or immunity in its perfected condition, is evidently of a different order, and may also very possibly have been developed on quite different lines, from that which we have been discussing in the human subject. In what this difference consists is at present unknown, and until we have a more intimate understanding of the actual condition in the system upon which immunity depends, or a closer insight into the particular agents responsible for its production we cannot hope to arrive at any definite conclusion.

There is, however, another obstacle to a logical acceptance of Wassermann's arguments as to the origin of protective diphtheritic serum in the human system, that is to say, in the light of our present knowledge, for it entails the supposition that such individuals have been subjected to the action of diphtheria bacilli. This supposition is the logical outcome of the bacteriological evidence which is at our present command on this subject. Thus it has been found, over and over again, that the serum of animals artificially rendered immune to a particular disease, is only efficacious in affording protection to other animals infected with *identically the same microbial disease*. This has quite recently been carefully worked out by Pfeiffer, who has shown that the serum of horses rendered immune to cholera is only efficacious in cases of infection from the cholera vibrio, and that it is absolutely inoperative in protecting from an infection due to any other vibrio, however nearly the latter may resemble that of the cholera vibrio.

But we have seen that protective serum may be possessed by individuals who have never had diphtheria, on whom, moreover, careful investigation has not been able to reveal the invariable presence of true diphtheria bacilli. So far it must be acknowledged, then, that we have no working hypothesis which enables us to comprehend aright the circumstances which determine the presence of or control the generation of anti-diphtheritic serum in the human system, and we are therefore powerless to either stimulate or diminish its production; but we are, however, in a position to regulate, to a great extent, the dissemination of diphtheria virus from one individual to another.

It has recently been shown that children taken from diphtheria surroundings, and not themselves suffering from the disease, in a large number of cases carry about with them in their nasal and throat passages typical virulent diphtheria bacilli, and that although they do not necessarily themselves develop the disease, they thus become the dangerous carriers of infection.

It is considered essential, therefore, that no member of a family where diphtheria has occurred, should be allowed to mix with others until a bacteriological examination has shown that diphtheria bacilli are absent from the air passages, neither are those who have recovered from this disease to be permitted to resume their usual occupations until the absence of diphtheria bacilli has been conclusively proved.

In Germany such systematic examinations are rapidly gaining ground, and already in some of the hygienic institutes the practice is regularly carried out. Indeed, in Königsberg, von Esmarch has suggested that to facilitate the universal adoption of such precautions, the throat of the patient or suspect should be wiped with a sterile sponge, and the latter forwarded for bacteriological examination.

The causes at present at work contributing to the generation of diphtheria in London have yet to be found.

If the contraction of diphtheria primarily depends upon the presence or absence of anti-toxic serum in the human system, then it would appear that some causes are at work tending to deprive the individual of the capacity to generate this means of protection.

It is difficult to conceive, and hard to realise, that the advance in sanitary science and improved hygienic conditions of the present day have but resulted in London in increased facilities for generating and distributing the virus of diphtheria, and that so far we have proved ourselves hopelessly unable to fathom this problem, or to stay the progress of this terrible malady.

REPORT OF THE COMMITTEE APPOINTED BY THE SMITHSONIAN INSTITUTION TO AWARD THE HODGKINS FUND PRIZES.[1]

THE Committee of Award for the Hodgkins prizes of the Smithsonian Institution has completed its examination of the two hundred and eighteen papers submitted in competition by contestants.

The Committee is composed of the following members Dr. S. P. Langley, Chairman, *ex-officio*; Dr. G. Brown Goode, appointed by the Secretary of the Smithsonian Institution; Assistant Surgeon-General John S. Billings, by the President of the National Academy of Sciences; Prof. M. W. Harrington, by the President of the American Association for the Advancement of Science. The Foreign Advisory Committee, as first constituted, was represented by M. J. Janssen, Prof. T. H. Huxley, and Prof. von Helmholtz; and after the recent loss of the latter, Dr. W. von Bezold was added. After consultation with these eminent men the Committee decided as follows:

First prize, of ten thousand dollars, for a treatise embodying some new and important discoveries in regard to the nature or properties of atmospheric air, to Lord Rayleigh, of London, and Prof. William Ramsay, of the University College, London, for the discovery of argon, a new element of the atmosphere.

The second prize, of two thousand dollars, is not awarded, owing to the failure of any contestant to comply strictly with the terms of the offer.

The third prize, of one thousand dollars, to Dr. Henry de Varigny, of Paris, for the best popular treatise upon atmospheric air, its properties and relationships. Dr. de Varigny's essay is entitled "L'Air et la Vie."

(Signed), S. P. Langley,
G. Brown Goode,
John S. Billings,
M. W. Harrington.

August 9, 1895.

Supplementary Report of the Committee Appointed by the Smithsonian Institution to Award the Hodgkins Fund Prizes.

After having performed the function to which the Committee was called, as announced by the circular of the Secretary of the Smithsonian Institution, dated March 31, 1893, which function did not include the award of any medals, there remained several papers to which the

[1] Communicated by Dr. S. P. Langley, Secretary Smithsonian Institution.

Committee had been unable to give any prize, and to which they had felt desirous to give some honourable mention, and on their representing this to the Smithsonian Institution, they had been commissioned to do so, and also to give certain medals of silver and bronze which had been subsequently placed at their disposition.

The Committee has decided that honourable mention should be made of the papers, twenty-one in number, included in the following list, which also gives the full names, titles, and addresses of the authors, and the mottoes or pseudonyms which in four instances were employed. To three of the papers a silver medal is awarded, and to six a bronze medal.

Honourable Mention with Silver Medal.

Mr. A. L. Herrera and Dr. Vergara Lopez, of the city of Mexico: "La Atmosfera de las altitudes y el bienstar del hombre."

Mr. C. L. Madsen ("Geo"), Helsigör, near Copenhagen, Denmark.

Mr. F. A. R. Russell, of London, Vice-President of the Royal Meteorological Society of Great Britain: "The Atmosphere in Relation to Human Life and 'Health.'"

Honourable Mention with Bronze Medal.

Mr. E. Deberaux-Dex and Mr. Maurice Dibos ("Spes"), of Rouen, France: "Études des courents aériens continentaux et de leur utilization par des párostats long-courriers."

Dr. O. Jesse, of Berlin, "Die leuchtendon Nachtwolken."

Dr. A. Loewy, of Berlin: "Untersuchungen über die Respiration und cirkulation unter verdünnter und verdichteter Sauerstoffarmer und sauerstoffreicher Luft."

Mr. Alexander McAdie ("Dalgetty"), of Washington: "The known properties of atmospheric air considered in their relationships to research in every department of natural science, and the importance of a study of the atmosphere considered in view of those relationships: the proper direction of future research in connection with the imperfections of our knowledge of atmospheric air and the conditions of that knowledge with other sciences."

Mr. Hiram S. Maxim, of Kent, England: "Natural and Artificial Flight."

Dr. Franz Oppenheimer and Dr. Carl Oppenheimer ("E pur si muove"), of Berlin, Germany: "Ueber atmosphärische Luft, ihre Eigenschaften und ihren Zusammenhang mit dem menschlichen Leben."

Honourable Mention.

Mr. E. C. C. Baly, of University College, London: "The decomposition of the two constituents of the atmosphere by means of the passage of the electric spark."

Prof. F. H. Bigelow, of Washington: "Solar and Terrestrial Magnetism and their relation to Meteorology."

Dr. J. B. Cohen, of Yorkshire College, Leeds, England: "The Air of Towns."

Dr. F., J. B. Cordeiro, of Washington:—"Hypsometry."

Prof. Emile Duclaux, of the French Institute, Paris, France: "Sur l'actinométrie atmosphérique et sur la constitution actinique de l'atmosphère."

Prof. Dr. Gieseler, of Bonn, Germany: "Mittlere Tagestemperaturen von Bonn, 1848-88."

Dr. Ludwig Hosvay von Nagy Ilsova, Professor in the Royal Joseph Polytechnic School, Budapest, Hungary: "Ueber den unmittelbar oxydirenden Bestandtheil der Luft."

Dr. A. Magelssen, of Christiania, Norway: "Ueber den Zusammenhang und die Verwandschaft der biologischen, meteorologischen, und kosmischen Erscheinungen."

Dr. A. Marcuse, of the Royal Observatory, Berlin, Germany: "Die atmosphärische Luft."

Prof. C. Nees, of the Polytechnic School, Copenhagen, Denmark: "The Use of Kites and Chained Air-balloons for observing the Velocity of Winds, etc."

Surgeon Charles Smart, of Washington: "An Essay on the Properties, Constitution and Impurities of Atmospheric Air, in relation to the promotion of Health and Longevity."

Dr. F. Viault, of the Faculty of Medicine, Bordeaux, France: "Découverte d'une nouvelle et importante propriété physiologique de l'Air atmosphérique (action hématogene de l'air raréfié)."

(Signed), S. P. LANGLEY,
G. BROWN GOODE,
JOHN S. BILLINGS,
M. W. HARRINGTON.

August 9, 1895.

THE PERSEIDS OF 1895.

THE conditions have been very unfavourable for the observation of this meteoric display. The moon's presence in the firmament overpowered the smaller meteors, and unfortunately the weather was very unsettled, the first half of August being notable for its frequent rains and clouded skies.

It was intended to obtain some observations at the end of July before moonlight interfered, but the attempt failed at several stations. On July 25, however, Prof. A. S. Herschel, at Slough, availed himself of a pretty clear interval between 11h. and 12h. 40m. to watch for Aquarids and early Perseids. He found meteors rather bright and plentiful, and the chief radiants in Cassiopeia, Camelopardus, Perseus, Aquarius, and Capricornus. At 11h. 32½m. an Aquarid brighter than Jupiter was recorded in a position a few degrees north of the head of Draco, and at 11h. 55m. a bright Capricornid, equal to Jupiter, traversed a long slow course from the north-east region of Cassiopeia.

On August 2, Mr. E. R. Blakeley, of Dewsbury, watched the sky from 11½h. to 14½h., and observed thirty-one meteors, of which seventeen, or slightly more than one-half, were Perseids with a radiant about 3° in diameter at $35\frac{1}{2}^\circ + 52^\circ$. Mr. Blakeley regards the declination as rather uncertain; it is probably 3° S. of the real position. The brightest meteors seen were Perseids; very fine ones were noted at 13h. 33m. and 13h. 45m.

On August 7, between 10h. and 12½h., some meteors were observed at Slough, Bridgwater, and Bristol. Prof. Herschel at the former place found them very scarce, however, for though the sky was quite clear from 10h. 50m. to 12h. only four meteors were detected. Mr. Corder, at Bridgwater, noted twelve in a watch of 2½ hours. Three or four of the paths indicated a good radiant at η Persei, but others seemed to come from just below γ. At Bristol the writer recorded seven meteors in 1¾h., and of these five were Perseids with a radiant at $41^\circ + 57^\circ$, which agrees with the usual position on August 7. Three meteors were observed at more than one station, and the particulars are as follows:

10h. 12m.—A swift, streak-leaving meteor of 2-3 magnitude observed at Bridgwater and Bristol. Height at beginning 43 miles over Bromyard, Hereford, and it disappeared at an elevation of 28 miles near Crickhowell, Brecon. The real length of path was 42 miles, and the earth-point at Barnstaple, Devon. The radiant was at $45^\circ + 47^\circ$, so that it was not a true Perseid, but a member of a well-known contemporary shower near α Persei.

11h. 4m.—A fine moderately swift meteor variously estimated as first magnitude, equal to α Lyræ, and Jupiter by observers at Bridgwater, Slough and Bristol respectively. Height at beginning 74 miles, at end 45 miles. The meteor passed from above Newport, Mon., to Gellygaer, Glam. Real length of path 33 miles. Earth-point 5 miles north of Pontardawe. Radiant at $333^\circ + 36^\circ$ in the south region of Lacerta.

11h. 29m.—A swift, streak-leaving meteor of second magnitude observed at Bridgwater and Bristol. Height at beginning 105 miles over Stratford-on-Avon, at end 63 miles over Oldbury-on-Severn. Real length of path 64 miles. Earth-point near Chumleigh, Devon. Radiant at $38^\circ + 57^\circ$, so that the meteor was a true Perseid.

On August 9, Mr. Corder, at Bridgwater, watched from 10h. 34m. to 13h. 45m., and saw about 30 meteors, nearly all of which were Perseids. He found the radiant indefinitely marked. A certain proportion of the meteors

observed agreed with a centre at 43 + 57°, but others were directed from η Persei, and others again from the cluster at χ Persei. On August 10 the writer, at Bristol, watched the eastern sky from 13h. 46m. to 15h. 17m., and saw 19 meteors, of which 17 were Perseids from a well-defined radiant at 45° + 55°. This is about 2° S. of the correct place. More meteors would have been seen but for the interference of passing clouds.

On August 11, between 10h. and 11h. at Bristol, 11 meteors were observed, including 7 Perseids with radiant at 44° + 58°. Clouds were again very prevalent, and greatly restricted the view.

On the same night, Prof. Herschel, at Slough, had a clear sky from 9h. 50m. to 12h., and mapped twenty-six meteors, a great majority of them being Perseids. Many of the meteors were bright, and Prof. Herschel regarded the maximum frequency as occurring on this date. "Besides Perseids, a few bright meteors diverged from Pegasus, Pisces, and the head of the Lynx. A pseudo radiant probably of the Perseids presented itself at 46° + 63½°. But the body of the Perseid radiation is very scattered—only the tail end of the shower being here recorded very likely—and a large area enclosing γ, τ, η, χ Persei and H, B, C, D Camelopardi, with its centre at about 43° + 58°, near k Persei, is the best approximation that can be gathered from the tracks registered."

A fourth magnitude meteor, moving swiftly, was seen at 10h. 7m. both at Slough and Bristol. Height at beginning, 78 miles; at end, 62 miles. It passed from over Brackley (Northampton) to Farringdon (Berks). Real length of path, 30 miles; earth-point, 10 miles south-west of Portland, Dorset. The radiant was at 48° + 60°, the meteor being a true Perseid.

From the various reports already received, it appears certain that this year's display has been far from presenting a conspicuous character. This has probably not proceeded from any special weakness in the shower itself, but from the unsuitable circumstances which have attended its return. Moonlight is a most serious obstacle in the way of meteoric work, and when, added to this, the observer is confronted with skies more or less clouded, the chances of success become very remote. But, in spite of these untoward conditions, the shower has by no means passed unobserved; many of its brilliant meteors have been recorded, and the radiant point has been determined on several nights. Some of the chief contemporary systems have made their presence known by some fine objects, and the results on the whole may be regarded as very satisfactory.

W. F. DENNING.

SIR JOHN TOMES, F.R.S.

ANOTHER of the small band of histologists, who took up the subject when the field was almost untrodden, has passed away, at the age of eighty.

Sir John Tomes, after serving an apprenticeship to a medical man at Evesham, came to London in 1836, and entered at King's College and at the Middlesex Hospital, being at the former a class-mate with the late Sir William Bowman, with whom a life-long friendship thus began.

For two years (1839-40) he resided in the Middlesex Hospital as house-surgeon; and even at this early stage in his career his attention became turned towards the histology of bone and teeth, and we find him feeding a nest of young sparrows and a sucking-pig upon madder. From a somewhat fragmentary diary which he kept, we find, too, that he then bought from Powell (afterwards Powell and Leland) a microscope, and that he was often spending his evenings with Bowman, Quekett, Kiernan, Todd, Carpenter, and Edward Forbes.

He was an early member of the Microscopical Society, and over a long series of years his contributions to the histology of the hard tissues were numerous. Amongst his more important papers in the *Phil. Trans.* were those on bone (in conjunction with the late Campbell de Morgan), on the dental tissues of marsupials, of rodents, and upon the structure of dentine, this last establishing the existence in dentine of the soft fibrils, ever since known as "Tomes' fibrils."

Like that of his friend Bowman, almost all of his work has stood the test of time, and to this day remains undisturbed. A strong bent towards mechanical invention led him, while still house-surgeon, to revolutionise the construction of tooth forceps, which thenceforward supplanted the old "key" instrument; and at the advice of the late Sir Thomas Watson, he determined to devote himself to the practice of dental surgery, in which the busiest years of his life were spent.

Dr. Morton, a dentist of Boston, Mass., having introduced the use of ether in 1846, we find from Sir John's diary that he was early in the field as an experimenter with this anaesthetic. After sundry experiences with it for tooth extraction at the Middlesex Hospital, some successful and some not, we read: "Gave ether to Arnott's case of lithotomy eight minutes, and insensibility came—the operation then commenced and lasted twelve minutes." (Jan. 14, 1847.) And after notes of many administrations: "Gave ether to eight patients for operations with great success. Earl of Cadogan (a governor of the hospital) and many others present." (Feb. 23, 1847.)

His lectures on dental physiology and surgery were perhaps the first in which the subject was treated from a true scientific standpoint, and when published became quite a classic. But it is curious to read in his diary a resolve that he really will not deliver any more lectures unless he has a class of at least six students.

In 1883 the College of Surgeons, exercising their right to confer honorary fellowships of the College, elected Sir John Tomes and the late Prof. Huxley.

In 1886 he obtained the honour of knighthood, in recognition of his great services to the cause of dental education, and to the establishment of a dental diploma and its recognition by Parliament, his unbroken success in all that he undertook being largely due to his excellent business capacity, and to the respect, trust, and liking which he inspired in all with whom he came in contact.

NOTES.

WE understand that a Civil List pension of £200 has been granted to Mrs. Huxley.

THE following have been elected Associates and Correspondents of the Reale Accademia dei Lincei:—National Associates, Prof. L. Luciani and Prof. G. Tizzoni; Correspondents, Prof. E. Cesàro, Prof. A. Ricco, and Prof. Carlo de Stefani; Foreign Associates in Mathematics, Prof. C. Jordan and Dr. G. Salmon; in Astronomy, Prof. Simon Newcomb; in Physics, Prof. H. J. Wild; in Morphology, Prof. A. Kolliker.

The following are among the recent appointments abroad:—Dr. R. Behrend to be Professor of Chemistry in the Technische Hochschule of Hanover; Dr. X. Siefert to be Professor of Forestry at the Technische Hochschule of Karlsruhe; Dr. F. Richarz to be Professor of Physics in the University of Griefswald; Dr. P. Stackel to be Assistant Professor of Mathematics in Konigsberg University; Dr. O. Wiener to be Professor of Physics in the University of Giessen.

REUTER'S correspondent at Wellington reports that a severe earthquake shock was felt at Taupo, in the district of Tauranga, and at some other places in New Zealand, on Saturday last. An earthquake was also felt over the greater part of Peru, but principally in the south, on Monday.

WE learn from *Das Wetter* that the efforts which have been made during the last fifteen years for the re-establishment of a

meteorological observatory on the Brocken, have at last been crowned with success, and, if unforeseen difficulties do not arise, it is expected that this important station will be in working order during the coming autumn. This successful issue is mostly owing to the support given to the undertaking by the Ministry of Public Worship and the Meteorological Institute of Berlin, and by the Brunswick and Hanover sections of the German and Austrian Alpine Club. There can be no doubt that observations from this mountain observatory will be of considerable value for the progress of meteorological science.

As already announced in these columns, the sixty-seventh meeting of German physicians and men of science will take place at Lübeck on September 16 to 21. Members and visitors will be received at the Town Hall on Sunday, the 15th, at 8 p.m. Business will commence on Monday at 11 a.m. in the Gymnastic Hall with a presidential address, followed by some medical papers. At 3 p.m. the sections will be formed, and at 7 p.m. there will be a social gathering at the Tivoli. Among the entertainments of the following days, are a garden party given by the Senate of the Free Hansa City of Lübeck on Tuesday, a grand ball in the theatre on Thursday, and an excursion to the lakes of East Holstein on the Saturday. Medical papers are announced by Drs. Klebs, Behring, Riedel, and Rindfleisch, and general scientific papers by Drs. Victor Meyer, Ostwald, and others. Senator Dr. Brehmer and Dr. Theodor Eschenburg are the secretaries of the meeting.

The *Board of Trade Journal* reports that an industrial exhibition, to celebrate the jubilee of the recognition of Berlin as the capital of the German Empire, is to be held next year in the Treptow Park, near that town, from May to October. The exhibition will embrace the following groups:—(1) Textile industries; (2) Clothing industries; (3) Building and engineering; (4) Wood industries (cabinet-making, &c.); (5) Porcelain, glass and fire-brick industry; (6) Smallwares and fancy goods; (7) Metal industry; (8) Engraving, the decorative arts, and the book trades; (9) Chemical industry; (10) Food products (including tobacco, spirits, &c.); (11) Scientific instruments; (12) Musical instruments; (13) Machine-construction, shipbuilding, and transport trade; (14) Applied electricity; (15) Leather and india-rubber industry; (16) Paper industry; (17) Photography; (18) Hygiene, and sanitary dwellings; (19) Education and instruction; (20) Fishing and boating, as industries and sports; (21) Riding and racing, aquatic sport; cycling, shooting and hunting, pleasure-boating; (22) Horticulture; (23 German colonial exhibition; (24) Hotel and restaurant trades.

The Council of the Federated Institution of Mining Engineers have had for some time under their consideration the holding of meetings of the student members, and the first meeting of students was successfully held in the North of England district on August 13, 14, and 15. With a view to interest the students more especially in the proceedings of the first meeting, a prize was offered by the Institution for the best essay on "The Prevention of Accidents in Mines." The prize was obtained by Mr. Austin Kirkup, whose essay deals concisely with the commonest forms of mining accidents, and sets forth the results of the experience of practical men on their prevention. Mr. Kirkup has based his facts almost entirely on the knowledge which practical experience and observation have afforded him, so his essay possesses a real value, and we regret that pressure upon our space prevents us from doing more than refer to it. In order that the meeting in connection with which the paper was prepared might be of a thoroughly practical character, the students who took part in the proceedings made lengthy underground visits to the Wearmouth and Eppleton Collieries, and were given every information as to the mode of working, haulage, ventilation, &c., practised at these extensive collieries. The Institution is to be congratulated upon its new departure, which is certainly calculated to give the students a wider knowledge of mining than they would otherwise obtain.

We have received the official programme of the prizes offered for 1896 by the Société Industrielle de Mulhouse. A prize of 1250 francs is offered for a complete history of one of the principal branches of Alsatian industry, such as spinning and weaving cotton and wool, printing woollen and cotton fabrics, machinery, &c. The Hubner prize, represented by a *médaille d'honneur* and 1000 francs, is offered for the best memoir on the carding of spun textile materials during the period which has elapsed since the last publication on the subject, or for the improvement which, in the opinion of the Society, shall have contributed most to the development of carding operations. Similar prizes are offered for a substance which, in the coloured cloth industry, can replace the dry albumen of eggs, and is cheaper than this substance; and for a colourless blood albumen which does not colour on steaming. Silver medals and prizes of 500 francs each are offered for a new and simple means of determining the amount of priming in steam boilers; for a new and advantageous mode of constructing buildings suitable for cotton and wool spinning and weaving, or the manufacture of dyed cloth; new and practical researches on the movement and cooling of steam in long conduits; a registering pyrometer for steam boiler fires; a memoir on the spinning of carded wool; and for a complete memoir on the drying of tissues. Besides these prizes, medals of various grades are offered in some 140 subjects connected with chemical and mechanical arts, agriculture, commerce, history, and fine arts. The competitions are international, but it does not appear from the programme whether French is to be the only language permitted. The memoirs, designs, samples, &c., must be marked by a device or motto chosen by the author, and addressed to the President of the Society before February 15, 1896, together with a sealed envelope containing the exact name and address of the competitor.

Mr. T. H. Bickerton pointed out, at the recent meeting of the British Medical Association, that when the inquiry was arranged into the disastrous collision between the *Elbe* and the *Crathie*, it was stated that "the question of the powers of vision will be carefully borne in mind in the Board of Trade inquiry into the cause of the collision." The inquiry has now been concluded, but it appears that the witnesses were not examined as to their eyesight. This act of negligence will need a deal of explaining. The reading of Mr. Bickerton's paper was followed by the adoption, on the proposal of Dr. Farquharson, M.P., of a resolution that the matter should at an early date be brought to the notice of Parliament, which should be asked to insist that adequate tests should be compulsorily applied before a lad is apprenticed to the sea; that the Royal Society's recommendations should be acted on by the Board of Trade in their entirety; and that officers already holding certificates, and now by the institution of adequate tests found colour blind, should have shore berths given them in Government offices.

The morphological place of moulds and yeasts, respectively, has long been the subject of speculation and research, some authorities regarding yeasts as having an independent existence, others considering them as only transitory forms in the life-history of moulds. Most important and interesting contributions to this subject have recently been furnished by the experiments carried on in Dr. Jorgensen's laboratory in Copenhagen. In the course of some researches on the diastatic power of the well-known Japanese mould *Aspergillus oryzae*, Juhler found that in the flasks in which this mycelium had converted rice-starch into sugar, it had produced a growth of typical alcohol

producing saccharomyces cells. This most interesting observation was subsequently confirmed by Jorgensen, who has since endeavoured to ascertain if the various types of alcohol producing yeasts can be traced to particular moulds, and already he has succeeded in demonstrating the evolution of wine yeast cells from a particular mould extensively present on grapes. Dr. Jorgensen intends to continue these most suggestive investigations, and publish his results from time to time in the form of a separate *Bericht* exclusively devoted to the work carried out in his laboratory. In pursuing these researches Dr. Jörgensen will not only render great practical service to the science of fermentation, but he will also lay botanists under deep obligation to him for having rendered possible a more extended and accurate insight into the life-history of moulds.

THE annual address on "The Recent Evolution of Surgery," delivered before the Medical Society of London in May last, by Mr. A. Pearce Gould, has been published in the form of a dainty brochure by Messrs. Kegan Paul and Co.

THE *Transactions* have reached us of the Ballarat meeting (1894) of the Australasian Institute of Mining Engineers. Among the papers contained therein, we notice a review of past and present steam pumping in mines, by Mr. J. Tipping; an address on the mineral wealth of Victoria, by Mr. James Stirling; an account of the physiography and geology of the Wadnaminga Gold Field, by Mr. F. D. Johnson; notes on the White Cliffs Offal Fields, Wilcannia, by Mr. F. G. de V. Gipps; and a description of ore-dressing by automatic machinery, by Mr. H. W. F. Kayser.

WE have received from Dr. G. Hellmann, of Berlin, a revised edition of "Meteorologische Volksbücher," which first appeared in *Himmel und Erde* in 1891 (see NATURE, vol. xliv. p. 185). The work contains an account of the earliest popular German treatises on natural science and meteorology from the first encyclopedia, "Lucidarius," which was written more than two centuries before the invention of printing, to the "Hundred-year Calendar" of Dr. Knauer, for the years 1701 1801. Dr. Hellmann has embellished the work by further biographical notes and additions based upon his laborious researches since the appearance of the first edition.

THE forty-first annual report of the Trustees of the Australian Museum is not a pleasing one. We read: "The continued smallness of the income allowed to the Trustees by Parliament has practically stopped the acquisition of specimens by purchase or collection. The amount expended in the purchase of specimens [during 1894] does not exceed £20. No collecting expeditions have been sent out, all that has been done in this way being confined to flying trips around Sydney. . . . The staff still continues at its reduced strength, and the forced economies of late years are beginning to tell on the efficiency of the Institution." It is really time that something was done to alter this unsatisfactory state of things; for the present conditions hamper the usefulness of the museum, and are most detrimental to the interests of science. A few researches have been carried on by the officers of the museum, and the mention of them gives a little light to an otherwise rather discouraging report.

MESSRS. GEORGE PHILIP AND SON have published a school edition of the "Systematic Atlas." The atlas has been specially arranged for the use of students in higher schools and training colleges. Though an abridgement of the "Systematic Atlas," it contains as many as 170 maps—practically all the general ones—in forty-one plates, and a complete index of more than 12,000 names. The atlas will be very valuable for class work in physical and political geography, and is a useful introduction to the larger edition, which has already been reviewed in these columns.

Another atlas, of which Messrs. Philip have just published a new edition, is the "Handy-Volume Atlas of the World," by Mr. E. G. Ravenstein. This, however, is almost a new work, for the whole of the maps have been re-drawn and re-engraved, and the letterpress accompanying them has been rewritten. We reviewed the original edition when it appeared some years ago; and it is only necessary now to say that the present volume, like its predecessor, is a compact and an efficient pocket-atlas.

THE second part of the fifty-first volume of the *Verhandlungen des Naturhistorischen Vereins der Preussischen Rheinlande, Westfalens und der Reg. Bezirks Osnabrück* (Bonn, 1894), contains six memoirs and a series of shorter papers and notes. The first memoir is a list of the fossils derived from northern regions found in the diluvial deposits of Westphalia, which is contributed by Dr. W. von der Marck. Laspreyes has issued a detailed study of the meteorites in the museum of the University of Bonn, in which the literature is tabulated with great care. Stockfleth describes the iron-ore deposits in the Hill of Huggel, near Osnabruck, where it occurs in the Zechstein. C. Roettgen gives a "Contribution to the Coleoptera Fauna of the Rhine Province." H. Pohlig continues his study of abnormal deer antlers by a description of two pairs belonging to the great Irish elk. One of these has a brow tyne on the left side, but no trace of one on the right, whereas the first of the serial tynes on that side is branched. In the other case both brow tynes are present, but the second serial tyne on the left side has a rudimentary branch. Dr. Verhoff contributes a short paper on the biology of the fire-fly *Phosphaenus hemipterus*. Among the smaller papers, a note by Ludwig gives a brief account of Marchiafava and Celli's work on the malaria parasite; Philippson summarises the geological problems that still await solution in Western Turkey. Schenck gives a brief demonstration of the structure of the Brazilian lianas, or climbing stems.

THE additions to the Zoological Society's Gardens during the past week include a Ruffed Lemur (*Lemur varius*, ♀) from Madagascar, presented by Mr. J. H. Bingham; a Vervet Monkey (*Cercopithecus lalandii*, ♀) from South Africa, presented by Mrs. C. J. Humphrey; a Mozambique Monkey (*Cercopithecus pygerythrus*, ♀) from East Africa, presented by Mrs. John Mahon; a Sooty Mangabey (*Cercocebus fuliginosus*, ♀) from West Africa, presented by Mr. Davies; a Sykes's Monkey (*Cercopithecus albigularis*, ♂) from East Africa, presented by Mr. J. Watkinson Brown; a Cheetah (*Cynælurus jubatus*), a Blotched Genet (*Genetta tigrina*) from Somaliland, presented by Mr. J. L. Harrington; a Martial Hawk Eagle (*Spizaetus bellicosus*) from British East Africa, presented by Captain B. L. Sclater; two Ravens (*Corvus corax*), two Buzzards (*Buteo vulgaris*), two Greater Black-backed Gulls (*Larus marinus*), European, presented by the Hon. William Edwards; a Herring Gull (*Larus argentatus*), British, presented by Mr. George Hawes; two Orbicular Horned Lizards (*Phrynosoma orbiculare*) from Mexico, presented by Mr. Bernard Jackson; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, a Black-backed Jackal (*Canis mesomelas*) from South Africa, four Spiny-tailed Mastigures (*Uromastix acanthinurus*) from North Africa, deposited; two —— Octodons (*Ctenodactylus gundi*) from Egypt, purchased, three Dorcas Gazelles (*Gazella dorcas*, ♀ ♀ ♀) a Sœmmerring's Gazelle (*Gazella sœmmerringi*, ♂), an Egyptian Cat (*Felis chaus*), three Libyan Zorillas (*Ictonyx lybica*), ten Varied Field Rats (*Isomys variegatus*), thirty-five Hairy-footed Jerboas (*Dipus hirtipes*), forty-five Lesser Egyptian Gerbilles (*Gerbillus ægyptius*), eight Larger Egyptian Gerbilles (*Gerbillus pyramidum*), two Egyptian Kites (*Milvus ægyptius*), a Cerastes Viper (*Vipera cerastes*) from Egypt, received in exchange; a Spotted Pigeon (*Columba maculosa*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE CŒLOSTAT.—The name *cœlostat* has been given by M. G. Lippmann to a modified form of siderostat which he has devised (*Comptes rendus*, No. 19, 1895, and *Observatory*, August). The special feature of the instrument is that it gets rid of the rotation of the field of view which disqualifies the siderostat for some purposes, such, for instance, as long-exposure photography. It consists simply of a mirror with its plane parallel to the earth's axis, and turning on a polar axis once in forty-eight hours in the same direction as the apparent diurnal motion of the heavens. It is easily demonstrated that the image of any star whatever will be seen stationary in a mirror so mounted, and a telescope pointed at the mirror in any direction will have a constant field of view. The telescope being directed to the cœlostat in a given position, to observe other objects having the same declination as that in view, it will only be necessary to turn the mirror; but for objects with different declinations the telescope must also be moved. If it be desired to use a horizontal telescope, it must be directed to the point on the horizon where the object rises, and the mirror must be started in a position suited to the hour-angle; but there is a limit to the use of a horizontal telescope. It is pointed out that the simplicity of the instrument makes it possible to turn it into one of great precision; stability being readily attained, while the possibility of flexure can be reduced to a minimum.

ADAMS' MASSES OF JUPITER'S SATELLITES.—A question having been recently raised by Mr. Marth as to the work of Adams on Jupiter's satellites, Prof. R. A. Sampson has stated the results of an inspection of the MSS. with reference to this subject (*Observatory*, August). It appears that when engaged upon a revision of Damoiseau's tables in 1875, with a view to their continuation, Prof. Adams determined the following revised values for the masses of the satellites:—

$$m = 0{\cdot}0000283113$$
$$m' = 0{\cdot}0000232355$$
$$m'' = 0{\cdot}0000812453$$
$$m''' = 0{\cdot}0000214880$$

"There is no reason to suppose that Adams attached any weight to the above determinations of the masses, seeing that he never published the values directly; the MS. appears to be little more than a study such as he was in the habit of making upon any work that he was examining, in order to test by cross verifications the accuracy and consistency of the whole. . . . Considerable expectations have been built upon the fact that Adams was engaged more or less closely for some years upon the theory of Jupiter's satellites. It will be well to say at once that the chief fruit of his attention was published in the *Nautical Almanac* of 1880; this, like all the rest of his published work, was the result of exhaustive labour, quite out of relation to the unpretentious form in which the outcome was presented, and only discoverable by searching tests."

ATMOSPHERIC REFRACTION.—The ordinary application of Bessel's expression for refraction requires that five quantities be taken from specially prepared tables, but Prof. E. C. Comstock, Director of the Washburn Observatory, has worked out a simple formula for computing the refraction without the aid of tables. A transformation of Bessel's formula, and the introduction of numerical constants from the Pulkowa refraction tables, leads to the following simplified form:

$$R = [2{\cdot}99215] \frac{BF}{455{\cdot}9 + t} \tan Z$$

$$\log F = -(42{\cdot}3 + 0{\cdot}12t)\tan^2 Z.$$

The number in brackets is a logarithm; B is the barometric pressure in English inches reduced to freezing-point; t is the temperature in degrees Fahrenheit, and Z is the zenith distance for which the refraction is required. The formula for F gives the logarithm in units of the fifth decimal place.

The computation by the formula is not more laborious than the direct use of the tables, and a comparison of the two methods shows that the differences in the results are far less than the uncertainty in the tabular numbers themselves. Prof. Comstock's paper forms one of a series of interesting "Studies in Spherical and Practical Astronomy," in the *Bulletin* of the University of Wisconsin (vol. i. No. 3).

ON THE ORIGIN OF EUROPEAN AND NORTH AMERICAN ANTS.

QUESTIONS belonging to zoogeography may be practical or theoretical, actual or genetic; ultimately the resolution of them, whatever they may be, takes its chief interest from their relations to genetical problems, that is, to the explanation of the origin of actual faunæ, and to the knowledge of the original home of phyletic groups, and of the ways followed in their gradual diffusion over the whole or part of the world. To this purpose, not only living animals, but also fossils, have to be determined, and their affinities exactly worked out; changes in the distribution of land and sea and in the shape of continental areas must be investigated, and analogies and differences in the diffusion of various groups of living beings taken in consideration, as far as they are known. The work involved is long and difficult, and its results will form the science of the future.

In a paper published in 1891, on the fossil ants of Sicilian amber,[1] I made out that at the beginning of the Miocene epoch, North and South Europe had very different faunæ of ants, the Sicilian amber containing genera which belong to the actual Indian and Australian fauna, but wanting the typical holarctic genera *Formica*, *Lasius*, *Myrmica*, which are found in the Baltic amber, some species of them being extremely common and abundant. A similar, but not such a striking, difference exists between recent Mediterranean and North European ants, the former including a greater percentage of Indian and cosmopolite forms, and an absolutely and relatively lesser number of typically holarctic ones, the most species of *Formica*, *Myrmica*, and *Lasius* not having reached Africa (*F. fusca*, L., and *M. scabrinodis*, Nyl., are introduced in gardens in Algeria), and these genera being scarcely represented in Mediterranean islands. After discussing these facts, I came to the conclusion that South Europe should have had in the Tertiary epoch an ant fauna compound of old Mesozoic cosmopolite genera (chiefly Ponerinæ), mixed with Indian-Australian forms. In North Europe these lived together with northern genera, which, after the emergence of the bottom of the middle European sea, invaded the South, being perhaps expelled from the North by gradual cooling of climate. Later, the glacial epoch destroyed in Europe nearly all the rest of tropical insects, their return being made impossible by the natural barriers of sea, deserts, and mountains, accumulated southward and eastward of our continent.

These studies I have carried a step further in a revision, now printed, of the Formicidæ of North America.[2] A great number of North American ants are specifically identical to European ones. My attention was directed to find differences between American and European specimens, and indeed but a few species were so similar to their European relatives as to be not distinguishable as sub-species or varieties. The one genus, *Epœcus* and two sub-genera are exclusively Nearctic; all the other genera of North American ants not represented in Eurasia (*Discothyrea* has two species only, one in North America, another in New Zealand) are Neotropical. The northern regions of Europe has the one peculiar genus *Anergates*, allied to *Epœcus*; middle and south Europe have two further genera not found in other parts of the world, and some others known from the Indian region. All these facts lead to the result, that the Palæarctic ant-fauna is made of cosmopolite + Arctic + Indian elements; that the Nearctic fauna is similarly composed of cosmopolite + Arctic + Neotropical ones.

The question that now arises is: how has such a mixture been effectuated—what changes have determined it? A complete and detailed answer I believe to be at present impossible; but the knowledge of the fossil mammals may help us greatly, supplying for the want of evidence taken from fossil ants, other than the Miocene fauna of European amber, the fossil prints of Formicidæ being too imperfectly known, and a careful revision of the existing collections from a trained specialist wanted. I believe that mammals and ants are both of the same age; their migrations took place by means of the same land connections, with the difference, that winged females of ants could, easier than terrestrial mammals, pass over sea-arms, being carried by winds.

I admit that in the Oligocene epoch, after Australia, Africa and South America had been cut off from a great northern

[1] C. Emery. "Le Formiche dell' Ambra Siciliana nel Museo Mineralogico della R. Università di Bologna." (*Memor. Accad. Bologna* [5], vol. v. 1. 1891).

[2] C. Emery. "Beiträge zur Kenntniss der Nordamerikanischen Ameisenfauna. (*Zoolog. Jahrbücher.* Abth. f. Syst. 7 Bd. pp. 633-682, Taf. 22; 8 Bd. pp. 257-360, Taf. 8. 1893-95)

system of dry land (such a system was rather an extensive archipelago than a continuous continent); this last was again divided into two systems: an Arctic and Occidental one, comprising North America, together with the northern parts of Asia and Europe, and an Indian one, communicating with South Europe. The former was the home of the Cervidæ, the rhinoceroses and most other Perissodactyls, the latter that of the Cavicorns and elephants. Very few mammals of Indian origin migrated into America; much more from the Arctic system into India. The same seems to be the case for ants. *Myrmecina* is perhaps the only North American genus of Indian origin (*Tetramorium cæspitum* being doubtless introduced by man), whereas a number of American-Arctic genera, sub-genera and species-groups, as *Myrmecocystus*, *Messor*, *Myrmica*, *Camponotus pennsylvanicus*, &c., are more or less far diffused in India and Africa, *Myrmica* reaching Borneo, and *Messor* the Cape of Good Hope.

In Europe, the study of the Baltic and Sicilian amber proves that the Arctic fauna went down from the north, as a host of conquerors, invading the territory formerly occupied by other people. I believe that, in Miocene times the North American fauna was much like the actual cosmopolite and Arctic part of the recent fauna, and might have included a number of forms actually extinct. As in the Pliocene a bridge was put between North and South America, an invasion of neotropical forms took place, walking from south to north. But it is not improbable that other forms migrated in the opposite sense, and descended from North America into the neotropical region. I suppose that such was the case for the genus *Pogonomyrmex*, perhaps also for *Dorymyrmex*, *Forelius*, and several species of *Camponotus*. It is not improbable that other genera from North America migrated southward, and later became extinct in their primitive home. The recent work of Mr. Scudder on Tertiary Curculionidæ of North America seems to confirm this view, some of these fossil beetles belonging to genera now living only in South America. It is probable that a number of insects, actually regarded as typical members of the neotropical fauna, immigrated from North America, as it is proved by palæontology for several mammals, as, for instance, the llama and alpacca of the Pampas.

The North American origin of some South American ants was suggested by Prof. H. von Jhering,[1] in a paper published last year. The author endeavours to sustain, by the study of the ants, his theory of the multiple origin of actual neotropical fauna. I agree in many points with him,[2] but I must recognise that the Formicidæ afford but little evidence in favour of his views. Actually, the ants of South America are distributed chiefly in relation to the climate and vegetation, no strong obstacles being put to the wide dissemination of the species, some of which range from Central America or from Mexico to Paraguay and Rio Grande do Sul. Chili is, however, an isolated country, which we may call "a continental island," although it is not surrounded by water. If we should take the Chilian fauna as a standard for the primitive fauna of v. Jhering's Archiplata, that should have been a very poor one, like the fauna of New Zealand, with which it offers a striking resemblance. The most characteristic feature of the Chilian ant fauna is the occurrence of peculiar species of *Monomorium*, like those inhabiting Australia and New Zealand, and of the genus *Melophorus*, found only in Australia and New Zealand. These facts corroborate the hypothesis of a Cretaceous or Eocene connection between South America and Australia.

New Zealand appears as a bit of old Australia, quite free from later Papuan or Indian intrusions, like Madagascar, which, as an isolated part of old Africa, has received but a few immigrants, when, at the Pliocene epoch, a stream of Indian life entered into the Ethiopian continent. Probably Chili may be considered as a part of ancient Archiplata, secured from Guyanean and Brazilian immigrants by the heights of the Cordillera, but having preserved only an incomplete set of the original Archiplatean fauna.

I state these facts for the purpose of making the main conclusions of a special work known to a wide public. Exact knowledge of the exotic faunæ, and especially of the fossils, may enable us in future to carry further these incomplete and in part hypothetical results. Similar studies made on single groups of animals and plants by specialists, which do not only accumulate by blind statistical work names of families, genera, and species, but deal with them, knowing the value of each, are highly desirable. Summarising and integrating the single results will build up an exact knowledge of palæogeography, and of the origins and interrelations of the faunæ and floræ of the world.

C. EMERY.

A NEW FILM HOLDER.

NO outdoor photographer can take a rough survey of the past few years without feeling some astonishment at the rapid progress made in nearly every branch of his art. The amateur is no doubt indirectly responsible for much of this advance; for it is through him that other brains have been set to work to satisfy all his many and various wants, in the way of instruments and accessories, to lighten his task at every step.

The camera, which a few years back was a heavy, clumsy and awkward instrument, is now of a light and handy construction, capable of being used in many cases without the tripod. Stops are now more generally of the Iris type, thus eliminating all possibilities of loss or of leaving them behind; while plate-holders are now supplied capable of holding a dozen or more plates, and necessitating the use of only one dark shutter.

The introduction of the film has brought us, however, into a new era; but the full benefit of this improvement can only be best appreciated by those who make use of their cameras while travelling.

Hitherto it has been impossible to make satisfactory use of the enormous advantages of celluloid flat films over glass plates; but now we have before us a holder which seems to give satisfaction, and which should prove a boon to photographers in general.

A holder to be really efficient should be readily adaptable to any ordinary camera; it must contain a large quantity of films,

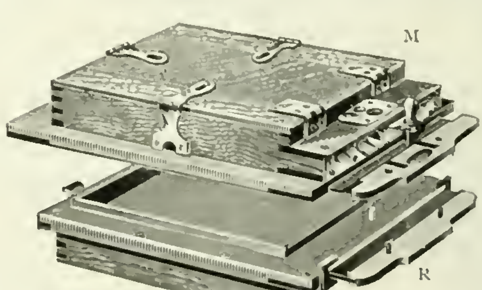

FIG. 1.—Magazine and receiver, separated.

and when complete and loaded should not be any larger or heavier than the three double backs (lighter if possible); and, finally, should be provided with some means of swiftly and automatically changing the positions of the exposed films.

Such a holder, if simple and of moderate price, would be much sought after by the photographic world. A very near approach to such an ideal film-holder will be found in that known as the "Frena," of which a short description follows.

Fig. 1 gives a complete view of the holder (the two parts are here shown separately), ready to be fitted to any camera. It consists of two parts: the magazine (M) and the receiver (R), each of these parts being about half as thick again as an ordinary dark slide. The exposure is made in precisely the same way as with an ordinary dark slide, namely, by inserting the magazine in the slide rails of the camera, and by withdrawing, and subsequently replacing, the shutter of the magazine.

The film changing is brought about simply by folding the magazine and receiver together until they interlock, drawing out the two shutters, pressing a change button to one side, and pushing the shutters back again.

The exposed films, stored in the receiver, may then be removed for development one by one, or as a complete pack, just as the operator desires.

An automatic counter upon the back of the magazine shows at a glance how many pictures have been taken.

The peculiarity of these films is that their edges are notched, and in their packing an alternate sequence is maintained as regards the position of these notches.

The films are supplied ready packed and arranged in the order in which they are to be inserted into the magazine.

To understand more clearly the position of the notches, it is best to take the empty magazine in hand, and entirely withdraw the black exposing shutter. It will then be seen that the front of the magazine is provided along its sides with two series of projecting teeth; it is upon these teeth that the films inserted into the holder are supported. At one end of the magazine, which we shall call the top, is a button; if this button be pushed from one side to the other, this movement will shift all the sorting teeth at the same time, so that they will occupy positions a little to one side of their former ones.

A film introduced into the magazine will then be supported by the sorting teeth, when these stand in the original positions; if this film be put into the holder with its notched corners towards the top end of the magazine. It will, however, fall past the sorting teeth, which pass through its notches, when the change button is moved to one side and the sorting teeth stand in the second position mentioned.

The process of filling the magazine is very simple, for the pressure-board has only to be removed, and the films inserted into the holder with the white film downwards, *i.e.* towards the pointers, and eventually towards the lens. Should there remain in the magazine any unexposed films, with their backings, and it is merely required to add to their number, the additional films with their backings may be dropped into the holder by twos or threes, due care being taken that the alternate arrangement be maintained.

The whole process, although somewhat lengthy to describe, is in itself very simple and neat, and can be at once grasped by an examination of the holder itself in daylight.

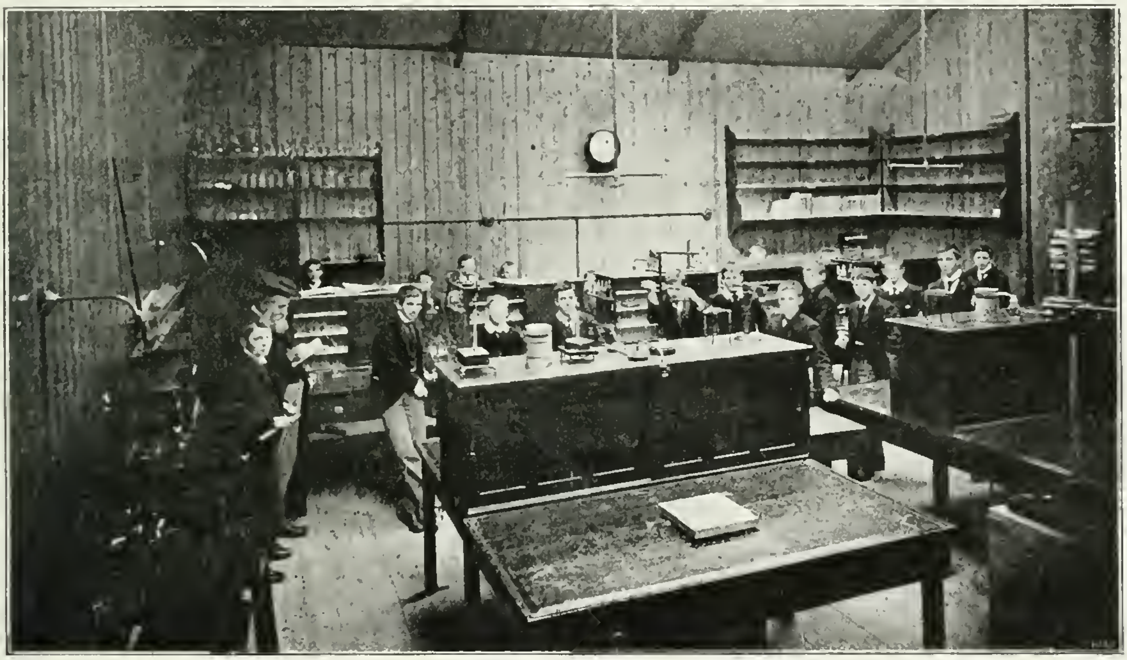
THE NEW NATURAL SCIENCE SCHOOLS AT RUGBY.

THIS new building for the physical part of natural science, which has recently been opened at Rugby School, is well worth a visit from any one engaged in teaching that subject. The building, owing to want of funds, is not at present of a permanent nature, being of the felt and matchboarding type, and in consequence has no pretensions to structural beauty; but when funds are forthcoming, no doubt the whole will be built in brick, and this will enable any alteration or improvement which may then be deemed necessary to be made. The building comprises a lecture room, a large laboratory, two small laboratories, an apparatus room, and workshop. At the back is another large room to be used for a natural history museum.

Every room is fitted with electric light and Ridge ventilation, which keeps the air pure even when filled with workers. The lecture theatre, which is capable of holding from 80 to 100 boys, is fitted with a solid slate table on brick piers, so that work can be done on it with the most delicate instruments without interference from the vibration of the floors. The fact that the rooms are all on the ground floor, gives the opportunity of putting all delicate instruments, such as balances, galvanometers, &c., on brick pillars, and thus to get rid of any vibration whatsoever.

The main laboratory contains ten tables for elementary physical measurements, two for calorimetry, two for magnetism, and two for heat experiments. Each table has a cupboard containing the necessary apparatus, and an electric lamp giving direct illumination on the tables without shadow or glare in the eyes of the worker.

Of the two smaller laboratories, one is an optical room, which can, of course, be completely darkened, and is fitted with two optical tables and a heliostat, so as to use direct sunlight as often as possible.



The other is the electricity room, containing two tables for frictional, and two for voltaic electricity, with cupboards, &c., as in the main laboratory.

Provision has been made for a small engine and dynamo for electrical work, and these will no doubt be added in time.

The whole is under the charge of Mr. L. Cumming, to whom the arrangement is due, and who is certainly to be congratulated on the result.

Every boy who takes up natural science at Rugby not only goes through a course of lectures, but has also to do experimental work himself in the laboratory. This enables him to grasp the subject much more thoroughly, and to remember it much better than if he attended the lectures only. That this method has had excellent results, will be seen by the number of successes in natural science that Rugby has gained of late years in scholarship and other examinations.

EVIDENCE OF A TWILIGHT ARC UPON THE PLANET MARS.

DURING last summer and autumn Mr. Douglass made at this observatory 341 micrometric measures of the diameters of Mars. In addition to their general value as micrometric measurements, these turn out to be of a peculiarly interesting

character. For on reducing them I find that beside furnishing, from their great number, relatively accurate values of the equatorial and polar diameters and of the polar flattening, they yield a by-product as unexpected as it is important. Their discussion reveals, in short, what appears to be unmistakable evidence of a twilight upon the planet, sufficiently pronounced to be visible from the earth, and actually to have been measured unconsciously by Mr. Douglass. That Mars possessed an atmosphere, we had what amounted to proof positive before; but that the fact should again be brought to light in this literal manner, as a silver lining to a cloud of figures, is a point of some curiosity. The measures had no such end in view; indeed, to detect the presence of an atmosphere by measures of the diameters had not suggested itself to any of the most adventurous of observers. Yet, as will be seen, the quantities upon which the evidence rests are so large as to be quite without the pale of accidental error, being ten times as great as the probable errors of observation, and twice as large as those that disclose the polar flattening. That they have hitherto escaped detection is due to their having been masked by another factor affecting the size of the polar diameter, as will appear in the course of this paper. To the unsuspected presence of these two causes, at times nearly offsetting each other, so far as relative values go, is attributable in all probability much of the discrepancy in the determinations of the polar flattening hitherto made.

The first measures were made on July 6, and the last on November 21, 1894. From October 12 they were taken nearly every night. Those here given were all made by Mr. Douglass. Later in the paper I shall introduce others by Prof. W. H. Pickering, which confirm the result. But here at the outset it may be well to point out that whether the results of many observers are to be preferred to those of one is, omitting discourteous personalities, a question entirely of what is to be determined. If the determination be one of absolute quantity, the more observers the better, provided they be good; but if, on the other hand, the determination be of relative magnitudes, one observer is better than many, as his personal equation obligingly eliminates itself, whereas two such equations can by no possibility, short of chance, eliminate each other. Now, in the present case, while the determination of the planet's size, and even to some extent of its polar flattening, are matters of absolute quantity, the evidence of a twilight upon it is one which rests upon relative results. The former, therefore, are subject to any systematic errors there may be; the latter, essentially free of them. In consequence, the by-product in this case is actually more trustworthy than the main results themselves.

Much care was taken in the matter of the Martian measures. In the ones I shall first discuss, those made from October 12 and November 21, Mr. Douglass adjusted the longitudinal thread of the micrometer, parallel or perpendicular, as the case might be, to the planet's polar axis, according to Marth's ephemeris, and then placed himself, so that the line joining his eyes was kept parallel to this thread or to the fixed transverse thread at right angles to it, during any one set of observations, the position being then recorded. As measures were taken in both positions for each diameter at various times, we have here a comparison of some eventual value. In eye-estimates such orientation in the position of the observer is absolutely essential in order to correct his possible astigmatism. Into measures, however, astigmatism enters only to cancel out. For if we consider the matter, it is at once evident that the whole field is distorted in the same proportion, the space between one turn of the micrometer and the next being reduced or expanded in the same ratio as the part of the image measured. The astigmatism thus eliminates itself.

From October 12 to November 21, Mr. Douglass made in all 275 measures; 140 of the equatorial, and 135 of the polar diameter. In the reduction of the measures, account has been taken of the place upon the micrometer screw at which the measures were made, and its appropriate value introduced. For by the forethought of Mr. Douglass in suspecting the possibility of variation, we measured the value of a micrometer turn at different points of the scale to confirm his conjecture.

Preliminary to the discussion of the results, it will be well to explain the corrections determined and applied. The first correction is that arising from refraction. This is the correction due to the differential effect of refraction upon the planet's opposite limbs at the extremities of the particular diameter measured. It depends both upon the altitude of the planet at the time of observation, and upon the inclination at that moment, of the particular diameter to the vertical. In many cases it was so small as not to make itself perceptible in the column.

The correction for aberration, similarly a differential effect, was so utterly insignificant throughout as not to appear at all.

The next correction is that due to irradiation. Toward its determination two different tests were made, in each case upon both Prof. W. H. Pickering and myself: in the one the effect should have been less than in the case of Mars, in the other greater. As in both cases the observers substantially agreed, the results may be accepted as having some impersonal value.

The first test was made upon a railroad switch-head, a white circular disc with a smaller black circle painted upon it. The size of these circles was unknown to the observers.

Their estimates were:

(W. H. P.) ... (white rim) ... 1 ; (diameter black circle) .. 1·3
(P. L.) ... ... ,, ,, ... 1 : ,, ,, ,, 1″·205

The discs and their distance were then measured and gave:

For diameter black circle ...	...	202 mm.
For radius white rim ...	...	126 mm.
For ratio	..	$1\frac{1}{4}$
For distance from eye ...	...	57 yds.

Therefore 1 mm. equalled 3″·9.

For the amount of the irradiation in seconds of arc, x, assume the amount of the irradiation of the white rim against the general background of earth of a brown colour to have been two-thirds that of the rim against the black circle. We have then, for the first observer, the following equation to determine x.

$$\frac{252 \text{ mm. } 10/3\,x}{212 \text{ mm. } 6/3\,x} = \frac{2\cdot0}{1\cdot3}; \text{ from which } x = 0\cdot2 \text{ mm. or } 36'';$$

for the second observer: $x = 40''$.

The second test was on the moon (November 22), when the old moon was seen in the new moon's arms. In this case the irradiation proved for both observers to be one-seventh of the radius of the old moon, or about 157″.

In the case of Mars, the value for the irradiation probably lies between these two limits. For the contrast between the Martian limb and the sky is pretty certainly greater than that of the white rim and the black circle of the switch-head, and less than that of the moon's bright limb and the sky, to which the contrast between the limbs of the old and of the new moon closely approximates.

It is to be noted that with a given illumination and a given eye, the irradiation correction is a personal constant, not depending upon the size of the disc measured and diminishing inversely as the magnification. In all the measures subsequent to and including October 15, the power used was 860; in those of October 12, it was 617. The correction, therefore, for all except those of October 12 was 0″·10; for those of October 12, 0″·14.

Such, then, is the correction for irradiation upon the planet's limb. The double of it, therefore, would need to be subtracted from the measures of a disc similarly placed to that of Mars when fully illuminated. But the disc of Mars was not fully illuminated even at the moment of opposition, and grew less so as time went on. Now it will be evident on consideration that the irradiation from the terminator must be very different from that upon the limb, inasmuch as the light fades away to nothing at the one, while it has its full value at the other.

To determine the amount of the correction needed at the terminator it is to be observed that if

γ = the areocentric angle between the sun and the earth;
α = the angle between the terminator and the point of the illuminated surface of which the irradiation is sought; and
m = the ratio of the irradiation at the limb to the radius of the disc, we have for the extent of the irradiation at the terminator

$$m\left(\frac{\sin\alpha}{\sin(\gamma+\alpha)}\right)^{\frac{1}{n}} - \left(\cos\gamma - \cos(\gamma+\alpha)\right)$$

where n denotes the ratio of the irradiation to the illumination, and is equal to about 2^6; that is, it takes 2^6 times the illumination to produce twice the irradiation effect. This value is got from inter-comparison of the above tests as limiting values, the

resulting value for Mars and the known decrease in illumination due to the telescopic magnification employed.

To deduce the resulting irradiation we must find the value of which renders the above equation a maximum, and then substitute this value in the equation. To do so directly leads to an equation of so high an order that approximation will be found the better, if indeed it be not the only, method of solution. By this means it appears that the necessary correction does not become insensible, to three places of decimals, till the phase angle, γ, somewhat exceeds 30°.

The formula must be used within the limits for which $\frac{\sin \alpha}{\sin (\gamma + \alpha)} = 1$; beyond them $\frac{\sin \alpha}{\sin (\gamma + \alpha)}$ must be taken as unity.

If the reflection from the disc followed the law of the cosines—that is, if the apparent illumination were always equal to the true one—we should have

$$m\left(\sin \alpha\right)^{\frac{1}{n}} - \cos \gamma - \cos\left((\alpha + \gamma)\right)$$

where α, γ, and n have their previous values, and m = a constant to be determined from the equation, from the value at the limb.

But although this is the formula for the case of a theoretical rough bare globe, it manifestly does not hold in the case of Mars, of which the limbs are not only as bright as the centre of the disc, but much brighter. The previous formula is, therefore, to be preferred to it, although even that formula makes the irradiation correction at the terminator too great as compared with that at the limb.

But it is to be specially noticed that no law of correction for irradiation at the terminator, however big it make that correction to be, is able to do away with the outstanding differences, presently to be noted, of the equatorial diameter at different times upon which the evidence of the twilight arc is based.

There is also the correction for phase. Inasmuch as the phase axis and the polar axis did not in general coincide, there entered into its determination beside the amount of the lacking lune, the angle of inclination of the two axes. So that the amount of the defalcation had to be calculated in accordance for each night. These corrections and their results reduced to distance unity have been calculated and tabulated.

Besides the above there is a fifth correction needed to reduce the diameter measured for the polar one, to the true polar diameter. The diameter measured perpendicular to this, or the apparent equatorial diameter, although not in fact an equatorial diameter, was always exactly equivalent to one, since its extremities were always each 90° distant from the pole. The other, however, was the diameter of the ellipse made by the plane passing through the polar axis, which was inclined to the polar axis by the angle of tilt, and needed, therefore, to be reduced to that ellipse's minor axis. This correction is best applied to the means, and appears in the subjoined table.

Twilight arc ... ... 10°
Polar flattening .. 1/191 of the equatorial diameter.

As previously explained, no correction is needed for astigmatism, as the measures themselves correct it.

So soon as the measures had been corrected and reduced to distance unity, two things became apparent, both so large as to be almost unmistakable before taking the means. The first was the polar flattening; the other an equally systematic difference in the size of the equatorial diameter according as the measures were made in October or in November. The November measures came out much larger than the October ones; while the corresponding polar measures, on the other hand, showed no corresponding increase. Struck by this fact, and suspecting its cause, instead of taking the mean of all the measures for each diameter, I divided them into sets according to their proximity in date to the time of opposition, and took the mean of these sets.

The means are as follows:—

Polar Diameter.

Mean October 15 to October 23, both dates inc.	9″·379
,, ,, 12 ,, 30, ,, ,,	9″·378
,, Nov. 2 to Nov. 21, ,, ,,	9″·390

Equatorial Diameter.

Mean October 15 to October 23, both dates inc.	9″·420
,, ,, 12 ,, 30 ,, ,,	9″·440
,, Nov. 2 to Nov. 21, ,, ,,	9″·545

Opposition occurred on October 20. The first set in each schedule, therefore, was made within four days of opposition; the second, within eleven days of it; the last, from fourteen to thirty-two days after it. That there is a systematic increase in the equatorial measures is apparent. That it is not paralleled by a corresponding increase in the polar ones shows instantly that it can hardly have been due to systematic error in the observer, since in that case both sets of measures should, in all probability, have been affected.

Now as all the measures had previously been corrected for refraction, irradiation, phase and tilt, the means of each diameter should have agreed with themselves. The polar did so in a very satisfactory manner; the equatorial not only did not, but they differed in proportion to their distance in time from the date of opposition. Now the only factor that increased in proportion to the distance in time from opposition was the phase. The direct effect in the way of decreasing the equatorial diameter had already, as we have seen, been allowed for; what is more, it is a correction susceptible of great accuracy, since it depends upon the motions and relative distances of the earth and Mars, quantities very accurately known. Besides these quantities, there is nothing which enters into the calculation but the position of the pole of Mars, and this would have to be, not only some 35 Martian degrees in error to explain the discrepancy, but would have had to have shifted obligingly to an opposite error during July and August to account for the measures taken then, as we shall see later. In other words, no such discrepancy exists.

In the case of a bare globe this direct effect would be the only effect phase could have upon the equatorial diameter; not so, however, in the case of a body not bare. If a planet possessed an atmosphere, that atmosphere would cause the phenomenon of twilight, and to an observer at a distance the effect of the twilight would be to prolong the terminator beyond what would otherwise be its limits. There would thus result a seeming increase in the equatorial diameter as the disc passed from the full to the gibbous phase. Now this increase is precisely the increase that the measures disclose.

It is furthermore worth noting that in the absence of an atmosphere, the measures of the equatorial diameter as the phase increased would not only have shown no increase, but would actually have shown a decrease, inasmuch as it would be impossible for an observer to see quite out to the edge under the diminishing illumination.

To determine the extent of the twilight thus disclosed by the measures, the angle between the radius to the sunset point and the radius prolonged to the point of the atmosphere last illuminated, had to be found. This enabled an equation to be developed, which gave for the visible twilight fringe an arc of 5°, the double of which, or 10°, is the angle which determines the duration of the twilight, or the twilight arc. On the earth this angle is 18°.

Applying the correction due to the twilight fringe, to the means previously obtained, we find the following close agreement between them:—

Polar Diameter.

October 15 to 22 inc.	9″·356
October 12 to 30 ,,	9″·354
November 2 to 21 ,,	9″·353

Equatorial Diameter.

October 15 to 23 inc.	9″·404
October 12 to 30 ,,	9″·396
November 2 to 21 ,,	9″·402

The value for the twilight band, deduced from these observations, does not measure the full breadth of that band. It gives rather a minimal value for it. For although Mars shows us a disc which is always more than half full, in which aspect an illuminated fringe of atmosphere would be more perceptible to an observer placed without than to one placed within it, provided both were at the same distance off, in the case before us the outsider is a great deal farther off. In consequence, what would be quite recognisable to one standing upon the planet's surface would be too faint to be seen by him at a distance of forty millions of miles away. The detection, therefore, of any twilight on Mars hints that the extent of that twilight is greater than appears; how much greater, we cannot at present say. A second possible cause affecting the extent of the twilight is the constitution of the Martian atmosphere. That atmosphere is practically cloudless; if, also, it be clearer than our own, the twilight would be relatively less for equal amounts of atmosphere, for the amount of twilight is, among other things, a question of the clearness of the air. In a perfectly transparent atmosphere there would be much less twilight than in one charged with solid or liquid particles.

It is to be noted that the evidence of a twilight is independent of any possible change in the value of the corrections. The only corrections that admit of uncertainty are those for the irradiation; and on examining them it will be seen that by no possible alteration can they be made equal to account for the observed increase in the equatorial diameter. Whatever alteration in them be assumed only affects somewhat the extent of the increase; it never does away with it. In other words, whatever these corrections, the fact of a twilight remains.

For the determination of the polar flattening, the measures of October 15 to 23 promise the best result, as the measures of the polar diameter on the 24th were so small, compared with those of the equatorial diameter, as to suggest error. Comparing, therefore, the polar and equatorial means of October 15 to 23, we get for the polar flattening 1/196. This, however, is probably too small; for though the polar cap was nearly non-existent during these observations, there were, on occasions, signs of its temporary reappearance, and an almost continuous brightness of the limb where it had previously existed. This by irradiation would increase the apparent polar diameter, and so decrease the resulting value for the polar flattening. If we compare each polar determination with its corresponding equatorial one, deduce the resulting polar flattening, and then take the mean of them all, we have for the polar flattening the value 1/191.

This is probably not far from the truth, although also probably a little too small, as the polar diameter was unquestionably still slightly increased beyond its real extent, by irradiation from the remains or consequences (vapour in the air, &c.) of the polar cap.

This value, 1/191, is also happily accordant with what theory would lead us to expect. Tisserand has found that with the known rotation of Mars and supposing homogeneity, the planet's flattening should be 1/175 of the equatorial diameter, while if the strata varied in density, after the manner of those of the earth, the polar flattening should be 1/227 of it. Now, assuming Mars to have been developed in general accordance with the nebular hypothesis, his strata would be neither homogeneous, on the one hand, nor, on the other, would they vary in density from the surface to the centre so markedly as is the case with those of the earth. For Mars being a smaller body, the pressure due to gravity would be less, somewhere between that of the earth and that of homogeneity, which is nothing, and the polar flattening should be somewhere between 1/227 and 1/175 of the equatorial diameter. 1/191 is, therefore, not far from the value probable *a priori*. It is interesting to have this result agree thus closely with theory, as it furnishes so much more reason for believing in the general evolution of our solar system.

Any value much less than 1/191 would require that Mars should have had at some time a much swifter axial rotation than he has now, which there is not only no ground for thinking, but much reason for thinking could not have been the case. For Mars lacks the tools for tidal friction, possessing insufficient satellites on the one hand and insufficient oceans on the other, so that even solar tides would be out of the question. Even had he possessed both requisites, it is more than doubtful if their slow action would have materially affected his form. For on the earth, which did possess them, we see that they were practically impotent to alter her shape. Any great change in Mars' period of rotation since he cooled must be looked upon, therefore, as unlikely.

For the final values of the diameters we have, allowing for a slight irradiation from the remains of the polar cap:—

True equatorial diameter	9″·40	″·007
True polar diameter	9″·35	″·007

It will be noticed how near these values are to that found by Hartwig from his general discussion several years ago.

We will now consider the September observations and the first of the October ones, those taken upon the fifth of the month. The first thing we notice about them is the abnormal size of the polar measures, so large as to suggest error. On examination, however, we find that instead of mistake they give us our first recognition of the cause that has so long masked the effect of the twilight fringe. The equatorial measures, it will be seen, come out in fairly good accordance with the October and November determinations, being greater than those taken near opposition, although somewhat smaller than the November ones, the discrepancies falling probably within the errors of observation. The polar measure of October 5 is also much what we should expect, but the polar measures of September 20 and 23 are apparently unaccountably larger. If we consider, however, the dates at which they were taken, we shall at once perceive a cause capable of producing the apparent increase. For in September and early in October the polar cap was still in existence. Now the south polar cap is eccentric to the pole, being situated some 5° from it, and from Mr. Douglass's micrometric measures of its position in October, in longitude 59°. As during the observations the south pole was tipped towards the observer, the polar cap was carried, in consequence of the planet's rotation, now in upon the disc, now out upon the limb. Now, if it chanced to be upon the limb at the hour at which the measures were made, its excessive irradiation would produce just such apparent increase in the polar diameter as was observed. On calculating its position for the hours of observation on September 20 and 23, it appears that at those times it was in fact upon the side of the pole toward the limb. Here, then, we have the *deus ex machina* in the matter. To clinch the conclusion, we find on calculating its position for the observation on October 5, when it suddenly measured small again, that at that hour the polar cap was upon the hither side of the pole. Such was also the case on October 12. The discrepancy thus stands accounted for. On October 13, very obligingly, the polar cap practically vanished just in time not to interfere with the most valuable measures at and near opposition.

That such is the explanation of the change in the polar diameter, comes out still more markedly from the July and August measures. Turning to those measures we find that the position of the polar cap is an all-important factor in them. Indeed, it is possible to follow its change of place upon the disc from its effect as reflected in the measures. This will appear at a glance from the accompanying diagram of the July and August measures of Mr. Douglass. A similar sequence of position and effect is apparent in Prof. Pickering's measures made at the same time.

COMPARISON OF POSITION OF POLAR CAP AND MEASURE OF POLAR DIAMETER.

The distance of the point from the medial line shows the angular position of the polar cap from the pole at the times of observation; 90 denoting its lower, and 90° its upper meridian transit. At its lower culmination it was at its nearest to the centre of the disc: at its upper, nearest the limb. The measures show the corresponding effect in irradiation.

			Polar.			
9″·85	10″·29	9″·57	9″.46	9″·41	9″·40	9″·34
			Equatorial.			
9″·67	10″·08	9″·48	9″·33	10″·03	9″·75	9″·41

			Equatorial.			
1000	1000	1000	1000	1000	1000	1000

At first sight it would seem that the later August measures do not support the rule. Closer consideration will, however, show that they do. For while in July the polar cap was still large, and in consequence reached to the limb, even when its centre was at some distance from it, by August it had dwindled to so small a patch as to be incapable of doing so when at the same angular distance away. Taking account of this fact, it will be seen that the effect is quite in accordance with the position, as comes out clearly in the relative values for the two diameters of August 14 and August 21.

It will now be evident why so large, and intrinsically so unmistakable, an effect as that of the Martian twilight should hitherto have escaped detection; the reason being that the twilight effect and the irradiation from the polar cap each increased their respective diameters to a simultaneous augmentation of both, conspiring each thus to mask the other.

Had measures been continued through a series of months, and been made in sufficient number, both causes must have made themselves evident. For both are periodic, and their periods are not the same. The irradiation from the polar cap has a primary period of thirty-seven days, a secondary one of a Martian year as well as a third depending on the tilt of the pole toward the earth; that of the twilight fringe a varying one of about thirteen months. But as previous measures have been made quite regardless of the twilight effect, and largely regardless of the polar cap, regardless, that is, of its varying position, the results have merely disagreed with each other, and the disagreements been credited to errors of observation. One result of this was discordance in the value of the polar flattening.

When we take both causes into account we find that the means of the July and August observations confirm the October and November ones.

For by comparing the values of the polar diameter when on and away from the limb, it is possible to deduce both the amount of the irradiation from the polar cap and the value of the twilight band from the measures themselves. The results in the case of Mr. Douglass agree with those of his October-November measures. In the case of Prof. Pickering, there is the same relative difference between the determinations, although the absolute values are all smaller.

That in the table the corrections to the July and August measures differ from those applied to the later ones, comes from the different manner of their taking; in the July and August measures the longitudinal thread of the micrometer having been set to the phase axis or perpendicular to it, instead of to the polar one.

In Mr. Douglass' determinations the value for the twilight arc comes out 8°. This is somewhat smaller than the result from the November measures. But a smaller value is precisely what should have been found. For the greater the phase angle, the less the foreshortening, which foreshortening by massing the illumination lets the fringe of light become evident farther out. Now the average phase angle was 43° in July and August, as against $18\frac{1}{2}$° in November.

From Prof. Pickering's measures the twilight arc comes out greater, or 11°, and by inference would have come out greater still in November.

Thus it appears that measures made by separate observers, and measures made before and after opposition, all confirm each other to the existence of a twilight band upon the planet.

PERCIVAL LOWELL.

THE FOUNDATIONS OF ENGINEERING EDUCATION.[1]

LET us consider what is the education which a young man needs to fit him for the profession of engineering, whatever be the special line of engineering which he proposes to follow. And, before discussing the details of what he ought to study, let us consider what it is that we desire to accomplish by giving him an engineering education. Naturally, we wish, as far as any education can accomplish it, to put him in the best condition to meet and grapple with the duties, the problems, and the responsibilities of his profession, as they arise.

There are two things which are absolutely necessary to make a successful engineer: first, a knowledge of scientific principles and of the experience of the past; and second, his own experience. The last cannot be given in a school, and each one must gain it for himself in his practice.

But the greater his familiarity with scientific principles and the experience of the past, the more able will he be to advance in his profession, and to be trusted to assume responsibility; indeed, if a man is ignorant of certain details and knows he is ignorant, he can—and if he is the right kind of a man, he will—take pains to learn them, if they bear on the work he has in hand; but if he is ignorant of scientific principles, it is very likely that he does not know he is ignorant, or, if by good luck he becomes aware of the fact, it is next to impossible for him to devote the time and study necessary to correct his ignorance while his mind is busy with his daily work.

Moreover, a man who is not familiar with the scientific principles which concern his work is not a safe man to trust with responsibility; for scientific principles are merely the laws of nature, as far as known, as shown by the experience of the past.

Hence it is that the first and most important thing to be done for the student is to give him a thorough drill in the scientific principles which find their application in his profession. It is in the school that this knowledge may best be acquired, since it is only with great difficulty that principles can be mastered after the student begins practice, and then as a rule but very imperfectly; and this view is borne out by those engineers who have been successful, and who have had to acquire their knowledge of scientific principles little by little, and as best they could, during the practice of their profession. Too much cannot be said by way of insisting that a thorough mastery of such scientific principles far outweighs in importance anything else that can be done for the student; and this is so true, that it is a decided mistake to neglect it in order to impart to him greater skill in such processes as will probably engage his attention the first year after he goes to work, as, for instance, to make him a skilful surveyor, a finished machinist, or an elegant draughtsman. Greater skill can far more easily be acquired after he goes to work than can scientific principles, and if this mistake is made the consequences will probably pursue him throughout his professional life.

The two fundamental sciences upon which the scientific principles of engineering are especially dependent are mathematics and physics, and no proper course in engineering can be arranged without insisting upon these fundamentals.

Let us begin with the subject of pure mathematics, and consider what portions should be studied, how they should be studied, or rather how they should be known, and of what service they are to the engineer after they have been mastered; bearing in mind that, in accordance with the opinions already expressed, the course of study should be laid out with direct reference to the needs of the engineer; and that when it is so laid out, it will, by the very fact that it leads to a definite end, subserve best the purpose of true education, and hence of developing the powers of the mind. Probably the best definition of mathematics is that given by Prof. Benjamin Pierce, who defined it as "the science of drawing necessary conclusions." This definition, of course, includes formal logic, and hence embraces more than is ordinarily understood by mathematics. We may assert, however, that the only function of mathematics is to draw necessary conclusions from the assumed data. Mathematics has nothing whatever to do with the correctness or incorrectness of the data. If these are correct, the conclusions deduced by mathematics will also be correct; whereas, if the data are false, the conclusions deduced by mathematics will be false.

Thus, if we require the sum of a certain set of numbers, the process of addition will give the correct result, provided the numbers added are the right ones; but if the numbers added are not the right ones, the result of the addition will not be the one desired. Indeed, we might compare pure mathematics to a mill; it will only produce good meal when the corn furnished to it to grind is of good quality; and if the corn is poor, the meal pro-

[1] Extracted from a course of lectures delivered in the Lowell Institute, Boston, by Prof. G. Lanza, Professor of Theoretical and Applied Mechanics, Massachusetts Institute of Technology, and published in the *Journal* of the Franklin Institute.

duced will be poor. With the selection of the corn which it is to grind, the mill has nothing to do.

No natural law can be discovered or proved by mathematics alone; the discovery or proof of natural law requires experiment and observation in all cases.

Just as arithmetic is a means of making calculations of certain kinds, so there are other kinds of calculations that can only be performed by the use of mathematics higher than arithmetic: some kinds require algebra, some geometry, some trigonometry, some descriptive geometry, some analytic geometry, and some the differential and integral calculus; while others yet require higher mathematics. Now, inasmuch as every one can easily understand the necessity of arithmetic for the purpose of making the calculations, and drawing the conclusions which come within its province: so, it follows that the engineer should have a thorough working knowledge of whatever portions of pure mathematics he needs, to make the calculations that are liable to arise in his work, and also to draw the necessary conclusions which concern the engineering and scientific subjects with which he must deal in his profession. This latter is an all-important matter; for, if our prospective engineer is to be fit to assume responsibility at some portion of his career, before he allows himself to use a formula in practice, he ought to know just how it is deduced, and what are the assumptions that were made in deducing it.

The rule-of-thumb engineer ignores this matter, and allows himself to risk the money, the safety, and the lives of his fellow men by making use of constants and mathematical formulæ found in some hand-book or elsewhere; using these constants and formulæ blindly, without knowing how they were deduced, or whether they have any reasonable foundation to stand on; or, in other cases, contents himself with merely guessing at what should be the dimensions of the various parts of a structure or machine. The natural result of such a course is poor work, and often disaster; and the world is rapidly waking up to this fact, so that important engineering work is being less and less entrusted to these rule-of-thumb engineers.

Now, I may say that knowledge of at least all these subjects mentioned in my communication—through the differential and integral calculus—is necessary for our prospective engineer.

As to descriptive geometry, that is classed by many, not as mathematics, but as a branch of drawing. It is the mathematical work upon which the making of engineering drawings of all sorts is based, and hence I have put it in this list.

So general has the conviction become that the engineer needs some knowledge of the differential and integral calculus, that it is not necessary for me to cite cases where he must use it if he is to perform his work intelligently and not by rule-of-thumb. Differential equations is a subject which is sometimes classed with the differential and integral calculus, and sometimes as a separate subject. It is one that should, if possible, be learned at least to a small extent, though the more that is known about it the better.

As to the special work to be done in each of these subjects, it is a matter of judgment with the one who lays out the course, and I shall not weary you with these details; but I must explain what ought to be the result aimed at, in other words, how the student should know his mathematics.

I might express my idea by saying that he should acquire the ability to use it as a tool, but, when I say that, I mean not merely as a tool for making computations, but also as a tool for drawing necessary conclusions of the kinds that apply to his engineering work; and this last is the feature which is most frequently lacking in the mathematical instruction given to engineering students.

By one method often pursued in teaching mathematics, the student is made to grind through a certain round of operations over and over until he has been so drilled in performing them mechanically that he can *perform* a similar problem. By this method, he is only taught to use it as a tool for making computations.

Another method, often pursued, is to exercise the student's ingenuity in performing a variety of (sometimes puzzling) problems which are of purely abstract interest, and are not planned in such a way as to bear upon the class of problems liable to arise in engineering work or study. This course probably tends to make the student do more thinking, but does not direct his thinking in the channel most useful for the prospective engineer. To accomplish the desired object in the teaching of mathematics, it is, of course, necessary that the teacher should be able to grasp the requirements of the engineering courses, and should know the special kind of use that the prospective engineer will have for his mathematics in later life.

Another important matter, the accomplishment of which concerns the treatment of the subjects of a mathematical nature that follow in his course, rather than the treatment of the pure mathematics itself (though the mathematical department can help in this matter), is that the student should be taught to distinguish between the mathematics of the work, and the assumptions made at the beginning, or in the course of it, respecting the proposition he is dealing with.

Perhaps I might sum up a part of the foregoing by saying that the student should be taught to think, and that the attempt to teach him to think should begin as early as possible in his course, and be kept up throughout. It is much easier for the average student to learn a lesson to recite by rote even if it contains a lot of formulæ, than it is to do a little solid thinking himself, and yet the more we can make him think the more successful in every way will he be.

Perhaps those of you (if there be any) who teach mathematics may think that the standard I have set is high. I admit that it is, and also that it requires hard work, good judgment, and the qualities of a good and efficient teacher, not only in laying out the course, but even more in teaching the class. Nevertheless, this standard is the one that is needed, and good judgment, and good teaching can at least approach near to it within the time that can be afforded in our engineering courses, even with such previous mathematical preparations as can be obtained to-day by the students before they enter the engineering schools; and as fast as it becomes possible to raise the standards of admission, the standard I have set can be even more fully realised.

The other fundamental science which I have mentioned is physics. It may be defined as that department of natural science which treats of the laws governing the various manifestations of energy (as gravitation, sound, heat, light, electricity, &c.). It deals with the natural law as it applies to just those classes of bodies, and substances with which the engineer does his work. Indeed, physics is a very general term, and might be made to include a great many subjects that are usually called by some more special name. For instance, mechanics is sometimes spoken of as a separate science, and sometimes as forming a part of physics, and, moreover, under any definition physics includes a part of mechanics.

Practically, a course in physics is the suitable preparation for a proper understanding of the scientific principles of most of the engineering work with which the student will come in contact. Treating, as it does, of the laws of nature, the more thoroughly an engineer knows it, the more successful will he be, and an ignorance of these laws can only result in failure.

Mechanics, light, sound, heat, and electricity, are all matters that concern the profession of the engineer so intimately that he cannot afford to neglect a careful study of their first principles. It is unnecessary for me to say, therefore, that there is no portion of the work usually treated in the best and most thorough courses of general physics but what should be included in the course of our prospective engineer.

Then, a certain amount of work in the physical laboratory is of great importance for the student, for it teaches him how to ask questions of nature, and how to get correct answers; in other words, how to make careful and accurate experiments, and this is a matter that intimately concerns the engineer. It is true that the greater part of his experimental work will have to be performed on a considerably larger scale than that usually carried on in a physical laboratory; but, on the other hand, some of his most important and delicate work involves the doing of just such experimental work as he is taught to carry on in a well-organised and well-equipped physical laboratory; and also the performance of these physical laboratory experiments is a proper introduction to his later course of experiments on the large scale, drilling him in accuracy and care while working on small amounts of material.

Indeed, I might mention quite a number of experiments which are all-important to the engineer, and in regard to which, it would be difficult to decide whether they should be called physical laboratory or engineering laboratory experiments, since they often have to be performed in both. Thus, the calibration of thermometers is a matter that is properly taught in the former, and yet the engineer who is to do delicate engineering work is liable to have to calibrate his thermometers, or at least to make a careful and accurate comparison with a standard which he or

some one else has calibrated. Again, the determination of the mechanical equivalent of heat is a matter of vital importance to the engineer, but the best and most accurate work thus far upon the subject has been done by Prof. Rowland, a physicist, in his physical laboratory.

As a rule, when experiments are to be performed on the large scale they get beyond the possibilities of a physical laboratory. In this category we may place such experimental work as the testing of steam engines and steam boilers, the testing of the strength of materials of construction on a practical scale, &c.; but, in order to carry out these tests with proper accuracy, we have generally to perform delicate measurements, as, for instance, measurements of temperatures, &c., in the first, and measurements of very small elongations or shortenings in the second case, and consequently have to use the suitable apparatus with the necessary degree of accuracy.

Since we have just been considering mathematics and physics, which may be called general sciences, perhaps a few words should be said in regard to chemistry. I cannot claim for it a similar position of fundamental importance in the engineering part of an engineering course that belongs to mathematics and physics. Nevertheless, a certain amount of chemical knowledge is of great importance to all engineers; but when they have passed this point, although a farther knowledge would be useful, it is not one of the most important things. The chemical composition of fuels, of steels and irons, of cements, of oils, and of other materials, is a matter that directly concerns the engineer. It is true that he can usually have his chemical analyses made for him, and generally would better do so; but he must know enough of chemistry to understand the bearing which the chemical composition of his materials have on their use in engineering work. Some knowledge of industrial chemistry is also desirable, so that he shall understand the nature of the processes performed in manufactories in which chemical processes on a large scale are performed.

The instruction in chemistry should, if possible, be given very early in the student's course. In the case of the Massachusetts Institute of Technology, and also, I think, in that of several other schools, both lectures and laboratory work in chemistry are given in the first year, and when this is done the instruction in chemistry fulfils another important function, viz. it introduces the student at the very threshold of his course to a species of scientific work that obliges him to think, and this, in a direction in which, as a rule, he has not been trained in the preparatory schools. Especially is this true of the laboratory work, for, by observing the results of experiments which he himself makes, he must learn how to interpret the replies of nature; and as chemistry, unlike mathematics, is an experimental science, it trains the thinking powers of the student even more than do his algebra, geometry, and trigonometry.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A PROSPECTUS of the course in practical chemistry at the Polytechnic Institute of Brooklyn has been received, and it indicates that very efficient work is carried on at the Polytechnic. The course, which is under the direction of Prof. P. T. Austen, appears to be adapted in every way to meet the wants of the day, and to train competent analytical and technical chemists. The claims of pure chemistry are also recognised, facilities being given for post-graduate work in it, as well as in applied chemistry and chemical engineering.

THE Department of Science and Art has issued the following lists of Scholarships and Exhibitions just awarded:—Whitworth Scholarships (tenable for three years), £125 a year each: Arthur H. Barker (24), engineer; George W. Shearer (21), apprentice engineer; Percy Nicholls (24), engineer; Harold R. Cullen (21), engineer. Whitworth Exhibitions (tenable for one year), £50 a year: Charles E. Goodyear (21), shipwright; George M. Brown (23), draughtsman; Norton Baron (22), engineering student; Harry Jackson (20), engineering student: Edward M. Leflufy (22), engine-fitter apprentice; Arthur E. Hyne (21), fitter apprentice; Robert McMillan (20), engineer apprentice; John W. Roebuck (23), fitter; George Follows (24), engineer; Arthur J. Baker (19), engine-fitter apprentice; William D. Ross (21), fitter; Frank H. Phillips (20), engineer apprentice; Henry T. Hildage (20), fitter; William P. Jones (25), marine engineer; John W. Milner (20), mechanical engineer; William Bayliss (20), apprentice fitter; John B. Shaw (21), engineer; James Walker (22), engineer; William H. C. Kemp (21), engineer apprentice; William J. Talbot (23), engineer; Henry C. Trigg (24), draughtsman; Duncan R. McLachlan (24), engineer; George A. Robertson (21), engineering student; Charles H. Imrie (22), engineer; William McG. Wallace (20), apprentice fitter; William J. Gow (20), apprentice fitter; William Lauder (20), draughtsman; Samuel A. Clarke (25), draughtsman; Edmund B. Ball (21), engineer student; Jabez W. Ashdown (20), engineer apprentice.

THE list of successful candidates for Royal Exhibitions, National Scholarships, and Free Studentships (Science) is as follows:—National Scholarships for Mechanics: Edmund R. Verity (19), student; George Patchin (17), engineering student; Harry Jackson (20), engineering student; William Ditchburn, jun. (19), teacher. National Scholarships for Chemistry and Physics: Thomas S. Price (19), student; Franz E. Studt (21), tailor; Herbert Bailey (18), student; William Bennett (16), student; John W. Barker (18), laboratory assistant. National Scholarships for Biological Subjects: Thomas G. Hill (19), student; Ernest A. Scott (17), student. National Scholarships: Charles E. Goodyear (21), shipwright; Edward M. Leflufy (22), engine-fitter apprentice; William H. James (22), student; William T. Clough (18), student; Herbert Halliday (22), student; William Cameron (18), laboratory assistant; Ernest Hibbert (15), student; Sidney E. Lamb (21), engine-fitter apprentice; Joseph Lister (19), teacher; William Parker (19), student; Ernest T. Harrison (18), laboratory assistant. Royal Exhibitions: George E. Clarke (17), student; Edward C. Hugon (16), student; Thomas G. Procter (19), engine-fitter apprentice; John A. Tomkins (20), scientific instrument maker; William T. Swinger (20), engineer; John W. Roebuck (23), fitter; Robert L. Wills (21), shipwright apprentice. Free Studentships: William D. Ross (21), fitter; Leonard W. Cox (21), student; Edgar R. Sutcliffe (20), engineer; William P. Jones (25), marine engineer; Percy M. Hampshire (19), lecture assistant; William J. Talbot (23), engineer.

SCIENTIFIC SERIALS.

Bulletin de l'Académie des Sciences de St. Pétersbourg, 5th series, t. ii. No. 4, April 1895.—Proceedings, in which we notice the discovery, by G. Schneider, in Prof. Kovalevsky's laboratory, of lymphatic glands in the earth-worm, *Dendrolæna rubida* (Crimea), and in *Perichæta*; as well as a communication by E. Burinsky, on his method of restoring by means of photography the writing in old documents which time has rendered invisible. A number of good negatives having been taken on collodion pellicules, they are superposed, and the visibility of the faintest markings is rendered still greater by means of a "contrast positive" obtained with regulated artificial light. Definitive researches into the variations of latitude at Pulkova, on the ground of older observations made with the great vertical circle, by A. Ivanoff (in French). The previous memoirs of the author on the same subject being considered as first approximations only, the definitive formulæ are now given. The observations of the years 1863–1875 and 1842–1849 are treated for that purpose separately. Both series lead to formulæ which agree very well with the formula given by Mr. Chandler in the *Astronomical Journal*, No. 322; however, the Pulkova observations of the first-named period seem to point to the necessity of slightly reducing the half-amplitude of the yearly term in Chandler's formula. Two long series of Pulkova observations thus fully confirm Mr. Chandler's conclusions. On the measurements and calculations of some photographic charts of the stars, by F. Renz (in German). A catalogue of all stars, down to the magnitude 11·0, which were occultated by the moon during the last eclipse, was given in the *Astronomische Nachrichten*. It appeared, however, that occultations of stars down to the twelfth magnitude could be observed at several observatories. Accordingly, the corresponding region of the sky was photographed by Prof. Donner with such an exposure (25 minutes) as to obtain the stars of twelfth magnitude as well, and F. Renz measured their positions with the Pulkova Repsold apparatus. The Potsdam photographs of the same region, made in 1891, were also re-measured, while the right ascensions of thirty-five fundamental stars were accurately determined at Pulkova with the meridian circle. The agreement between the different plates is quite satisfactory; and no distortion of the field could be detected. However, there are certain small systematic errors which cannot yet be well

explained. Thus, the right ascensions on plate i. are on the average by 0·047s. greater than the values deduced from plate ii.—The Arachnides collected by G. Potanin in Mongolia in 1876-1879, by E. Simon (in Latin). Part i. Araneæ and Opiliones: forty-one species are mentioned and described, nineteen being new species.—Do the spurs of the Carpathians penetrate into European Russia? by General A. Tillo (in Russian). The question is answered in the negative. Supan and Lehman, in Kirchhoff's "Landerkunde von Europa," trace the limits of the Carpathians outside the boundaries of Russia: so also the Russian geologists, Barbot-de-Marny and Karpinskiy, did not see continuations of these mountains either in Poland or in Russia. The new hypsometrical map, now compiled by the author on a larger scale (27 miles to the inch), confirms this view.—New or little known Ixodidæ in the museum of the St. Petersburg Academy, by A. Birula (in Latin). Eight new species are described and figured on two plates.

Memoirs (Trudy) of the Kharkoff Society of Naturalists, vol. xxvii., 1892-93.—Obituary of I. Th. Levakovsky, by A. Guroff, with a portrait.—Researches into the crystals of kermesite and uranotil, by P. P. Piatnitzky.—The Algæ of the bays and peat-bogs of the Dnieper, in the government of Poltava, by M. Alexenko. This flora is poor, the *Cladophora*, *Confervæ*, *Enteromorpha*, and *Ulotrix* prevail, while Desmidiaceæ and Protococcoideæ are very rare; 371 species are mentioned.—The flora of the Central Caucasus, by I. Akinfieff, part i. (see Notes, vol. lii. p. 304).—On the part played by hydrocarbons in the inter-molecular respiration of higher plants, by W. Palladin. It had been shown by Diakonoff (*Ber. d. deut. bot. Ges.*, 1866) that certain fungi give up carbonic dioxide during their inter-molecular breathing, only when the surrounding feeding medium contains a substance capable of fermenting. It was desirable to verify whether the same is true with higher plants, but the difficulty was in the fact that the cellular sap always contains glucose, which itself is capable of fermenting. By a series of experiments on etiolated leaves, the author now confirms Diakonoff's conclusions for higher plants as well.—Short preliminary notes in the Addenda. Vol. xxviii., 1893-1894.—Geological description of Kharkoff town, with map and profiles, by P. Poustovitov.—On the part played by the secondary parallel chains in the grouping of forests and steppes in West Caucasus, by A. Krasnoff. An answer to G. Akinfieff's criticisms.—Materials for the Algæ flora of the government of Kharkoff, by M. Alexenko; 407 species are described.—Preliminary report on a geological excursion in the government of Kherson, by P. Piatnitzky.—Biological observations, by W. Taliev. A series of various observations of facts relative to the life of plants, which have hitherto attracted but little or no attention, chiefly relative to fertilisation, colouration, movements of plants, and heliotropism in connection with the affluence of sap.—On the flora of the basin of the Chakva, by A. Krasnoff, being a preliminary report of a botanic excursion into the province of Batum, containing an excellent general description of the vegetation, poor in species, but attaining a luxurious development of the individuals.—On the lichens of the neighbourhoods of Kharkov, by W. Tschernov; fifty-five species are described. Chemical studies on the seeds of *Myristica fragrans*, by W. Palladin, being a note on a special substance which is found in several seeds, but neither in the leaves or in the twigs, and which is now studied in Prof. Schultze's laboratory at Zurich. Preliminary report on botanical researches in the Verkhnedniepróvsk district of Ekaterinoslav, by I. Akinfieff; twenty-six species, new for South Russia, have been discovered.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 12.—M. Marcy in the chair.—Observations of planets made at Marseilles Observatory, by M. Coggia. The observations were made with the 0·26 m. equatorial, and for the planets BZ and CA (Charlois).—On algebraical surfaces which admit a continuous group of birational transformations, by M. Paul Painlevé.—On a special microscope for the observation of opaque bodies, by M. Ch. Fremont. The novelty in the microscope described, consists essentially in the method used for obtaining vertical illumination of the object, applicable with high powers. A concave mirror is arranged obliquely *inside* the microscope tube to reflect downwards a beam of light entering at a side aperture in the tube. The light passes through a prism which reduces the rays to parallelism with the axis of the microscope and then through the lenses of the objective to the object. The concave mirror and the prism are pierced centrally by a conical tube along which travel the rays of light from the object, the image being formed and magnified by the eye-piece in the usual way. M. Marey remarked on the great use the new modification would have in the chrono-photographic study of the movement of microscopic beings.—On some melting and boiling points, by M. H. Le Chatelier. From the experiments made, it is probable that the melting point of gold determined by M. Violle to be 1045°, is a little low. The error is certainly not more than 20°, and the results so far obtained would not justify the alteration of the pyrometer scales in actual use.—On certain potassium derivatives of quinone and hydroquinone, by M. Ch. Astre. A number of potassium derivatives are described, concerning which it is stated: the action of metals on quinone, together with the existence of oxy-potassium compounds yielded by quinone and hydroquinone (to be described in a coming paper) confirm the diketonic nature of quinone. The formation of these compounds and the passage of some of them from the hydroquinone to the quinone series, allow a formula to be given to quinone clearly expressing its diketonic character and accounting for its numerous reactions.—A theorem concerning the separation of the roots of numerical equations of every degree, by M. Teguor.—A white rainbow, by M. E. Kern. A lunar rainbow observed at 10 p.m. August 5.

BOOKS, PAMPHLET, and SERIALS RECEIVED.

Books.—British Birds: W. H. Hudson (Longmans).—Lectures on Elementary Navigation: Rev. J. B. Harbord (Potter).—Polyphase Electric Currents and Alternate-Current Motors: Prof. S. P. Thompson (Spon).—Transactions of the Australasian Institute of Mining Engineers, Vol. 2 (Adelaide).

Pamphlet.—The Recent Evolution of Surgery: A. P. Gould (K. Paul).

Serials.—Journal of the Chemical Society, August (Gurney).—Proceedings of the Physical Society of London, August (Taylor).—Bulletin of the American Mathematical Society, July (New York, Macmillan).—Natural History of Plants: Kerner and Oliver, Part 15 (Blackie).—Bulletin de L'Académie Royale des Sciences, &c., de Belgique, 65e Annee, No. 6 (Bruxelles).—Astrophysical Journal, August (Chicago).—Royal Natural History, Part 22 (Warne).

CONTENTS.

THURSDAY, AUGUST 29, 1895.

SIR SAMUEL BAKER AND NORTHERN AFRICA.

Sir Samuel Baker: a Memoir. By T. Douglas Murray and A. Silva White. 8vo. Pp. xii. 447, with six illustrations and nine maps. (London: Macmillan and Co., 1895.)

North Africa. Stanford's Compendium of Geography and Travel. (New series). *Africa.* Vol. i. By A. H. Keane. 8vo. Pp. xvi. 639, with seventy-seven illustrations and nine maps. (London: E. Stanford, 1895.)

A SUMMARY of our present knowledge of Northern Africa, and a memoir of the late Sir Samuel Baker, may be appropriately considered together, for Baker's main title to fame rests on the work he did in that region: and had his experience been properly utilised, the most interesting part of it might not have been lost to civilisation and closed to scientific inquiry.

Samuel White Baker came of an old Devonshire family, members of which have done good work for their country since the time when Sir John Baker served Henry VIII. as Attorney-General, Chancellor of the Exchequer, and Speaker of the House of Commons. Baker was born in London on June 8, 1821, and spent most of his early life at Enfield. He was destined for a commercial career, and in 1842 placed in his father's office in Fenchurch Street. But the work was utterly uncongenial to him. His marriage kept him quiet for a time, but not for long; for next year he gave up business and went to Mauritius, where the family had estates. In 1846 he went for a shooting expedition to Ceylon, and was so impressed by the possibilities of the island, which then had a very bad reputation, that he resolved to found a colony in it. In 1848 he led a party of settlers to Newera Eliya, where 1000 acres of land had been bought from the Government. This was cleared, and a settlement made. Baker remained there till 1855, and during his stay did a good deal of big-game shooting. In 1856 his wife died, and as he had previously lost three of his children, he became very depressed, and actually resolved to enter the Church. This scheme came to nothing, and Baker accepted instead the post of manager of the Dobruscha Railway, the construction of which had been just begun. This kept him busy in 1859 and 1860, and raised in him the keen interest he afterwards felt in the Eastern question. It was in the next year, when Baker was forty years of age, that he resolved on an expedition into Africa to try to meet Speke (whose sister had married Baker's father) and Grant, and carry out some explorations to supplement theirs. In order to gain experience of the people and to learn the languages required, he made a preliminary excursion up the Atbara to some of the Abyssinian sources of the Nile. He left Khartum on his main expedition on December 18, 1862, reaching Gondokoro in the following February. Here he met Speke and Grant, who returned northward in Baker's boats, while he and his heroic wife continued their journey southward along the Nile valley, and through Unyoro till they reached the Albert Nyanza at Bakovia. The discovery of this lake was the greatest achievement of the expedition; but it was only the accident of the condition of the weather, that robbed them of the discovery of the snow-clad peaks of Ruwenzori. They had reached a point whence, in clear weather, the mountain ought to have been as visible "as St. Paul's dome from Westminster Bridge," as Stanley said. They returned to Europe in 1865, and in 1869 went back to the Soudan on an expedition to suppress the slave trade. Baker had all a Devonshire Quaker's horror of this trade. The view that slavery was a kind of secondary larval structure, necessary in a certain stage of national progress, and later on to be absorbed or thrown off, was not then recognised. Baker simply regarded it as an unholy thing, which was to be crushed by any means or at any cost. He accordingly went for it with the pluck of a bull-dog, and just about as much judgment. He was given a commission to go to the Soudan to break up the gangs of slave raiders. He had an independent command, but could do little of permanent value without the assistance of his colleague, the Governor of Khartum; but this worthy official, as well as Baker's native assistants and the supreme authorities in Cairo, all believed in the slave trade in theory, and carried it out in practice. Ismail Pasha alone seems to have been sincere, and not to have endeavoured to thwart the efforts he was ostensibly supporting. Thanks, however, to Baker's indomitable pluck and energy, and his tact with the men, this Quixotic expedition was carried through with a certain measure of success. Its commander alone benefited much by it, for he secured a great reputation as a leader of men, and learnt better to understand both the Soudan and the slave trade. He returned to Europe in 1873, recognising the futility of trying to effect a social revolution over several millions of square miles by shooting a few score of the agents in a trade, of which the principals lived unpunished in Cairo and Khartum. He realised that the only useful course was to improve the industrial conditions, so as to render slavery unnecessary. Had Baker been sent back to the Soudan, and allowed to work on these lines, the subsequent revolt might have been avoided. But the task was entrusted to other hands, and unfortunately Gordon's peculiar genius was less successful with Mohammedan fanatics than it had been with the stolid Chinese.

After Baker's return he settled at Sandford Orleigh in Devonshire, where he lived till his death, except that every winter he made expeditions to some warmer clime. He was always ready, like a knight-errant of old, to rush forth to relieve the inhabitants of some village on the Brahmapootra from the tigers that preyed upon them. He was fond of sport to the last; even after he had become too unsteady to be a match for anything worse than the worn-out old tigers who have had to turn "man-eaters."

The story of Baker's life is pleasantly told, and even in less competent hands could not have failed to be interesting. The editors have wisely left Baker to relate most of it by quoting copious extracts from his letters. Explanatory chapters help the reader to understand the condition of African geography at the time of his journeys, and to appreciate the relative importance of his work. These chapters seem to be judicious and well informed. Our main regret is that we do not hear enough of Baker as

T

a sportsman and a naturalist. One chapter is devoted to this, but we doubt if it does full credit to Baker's work in this field. His valuable contributions to natural history are barely referred to; his important services to gunnery and his improvements in cartridges are not mentioned. We should have been glad to have seen more space devoted to this, at the cost of condensation of the political writings, some of which are hardly likely to add to his reputation. For when we remember the conditions under which he shot, the clumsy old muzzle-loaders and the badly-mixed powders he used, and the accuracy and fulness of his observations upon the habits of animals, we cannot but reckon Baker as the greatest of English sportsmen.

While Baker's memoir gives an account of the political conditions of the Soudan from 1860 onward, Prof. Keane's admirable summary of the present knowledge of North African geography completes the sketch in other departments. He divides North Africa into six divisions, viz. the Atlas (including Morocco, Algiers and Tunis), the Sahara, the Soudan and the Niger Basin, Egypt and Nubia, and Italian North-East Africa (including Abyssinia and Somaliland). Each of these districts is described separately, an account being given of its general physical geography, of its history, as far as this is known, of its ethnography, and natural history. The ethnographical sketches are especially well done, while the political histories are the most detailed. The natural history is the least satisfactory part of the book. The geology is mostly quoted second-hand, or is taken only from geographical instead of from geological papers. Some of the botanical records are certainly quite untrustworthy, as when on p. 533 *Casuarina* is reported on the banks of the Webi Shebeyli, whereas it occurs only on the ends of the promontories on the eastern coasts. The nine maps are admirably clear, while full of information. The volume is in every way a great improvement on the preceding editions. The immense increase in the material to be summarised, has made the task a difficult one. This enormous growth of knowledge applies, however, to five out of the six districts described. It is only in one that progress has been stopped, and of which the new edition has nothing fresh to report, except paper delimitations in Europe and reaction in Africa. All Junker's collections, the greatest ever made in the equatorial provinces of Egypt, were lost by the closing of the Soudan. It is to be hoped, however, that European officials will not much longer prohibit our representatives in the field from taking action, and again opening to progress the lands where Gordon's death and Baker's life-work added their names to the roll of our national heroes.

J. W. G.

BIO-OPTIMISM.

(*The Evergreen. A Northern Seasonal.* Published in the Lawnmarket of Edinburgh by Patrick Geddes and Colleagues. London: Fisher Unwin, 1895.)

It is not often that a reviewer is called upon to write art criticism in the columns of NATURE. But the circumstances of the "Evergreen" are peculiar; it is published with a certain scientific sanction as the expression of a coming Scots Renascence of Art, and it is impossible to avoid reference to its æsthetic merits. It is a semi-annual periodical emanating from the biological school of St. Andrews University. Mr. J. Arthur Thomson assists with the proem and the concluding article ("The Scots Renascence"), and other significant work in the volume is from the pen of Prof. Patrick Geddes. It may be assumed that a large section of the public will accept this volume as being representative of the younger generation of biological workers, and as indicating the æsthetic tendencies of a scientific training. What injustice may be done thereby a glance at the initial Almanac will show. In this page of "Scots Renascence" design the beautiful markings on the carapace of a crab and the exquisite convolutions of a ram's horn are alike replaced by unmeaning and clumsy spirals, the delicate outlines of a butterfly body by a gross shape like a soda-water bottle; its wings are indicated by three sausage-shaped excrescences on either side, and the vegetable forms in the decorative border are deprived of all variety and sinuosity in favour of a system of cast-iron semi-circular curves. Now, as a matter of fact, provided there is no excess of diagram, his training should render the genuine biologist more acutely sensitive to these ugly and unmeaning distortions than the average educated man. Neither does a biological training blind the eye to the quite fortuitous arrangement of the black masses in Mr. Duncan's studies in the art of Mr. Beardsley, to the clumsy line of Mr. Mackie's reminiscence of Mr. Walter Crane, or to the amateurish quality of Mr. Burn-Murdoch. And when Mr. Riccardo Stephens honours Herrick on his intention rather than his execution, and Mr. Laubach, rejoicing "with tabret and string" at the advent of spring, bleats

> "Now hillock and highway
> Are budding and glad,
> Thro' dingle and byway
> Go lassie and lad,"

it must not be supposed that the frequenters of the biological laboratory, outside the circle immediately about Prof. Patrick Geddes, are more profoundly stirred than they are when Mr. Kipling, full of knowledge and power, sings of the wind and the sea and the heart of the natural man.

But enough has been said of the artistic merits of this volume. Regarded as anything more than the first efforts of amateurs in art and literature (and it makes that claim) it is bad from cover to cover; and even the covers are bad. No mitigated condemnation will meet the circumstances of the case. Imagine the New English Art Club propounding a Scientific Renascence in its leisure moments! Of greater concern to the readers of NATURE than the fact that a successful professor may be an indifferent art editor, is the attempt on the part of two biologists (real responsible biologists) writing for the unscientific public, to represent Biology as having turned upon its own philosophical implications. Mr. Thomson, for instance, tells his readers that "the conception of the Struggle for Existence as Nature's sole method of progress" "was to be sure a libel projected upon nature, but it had enough truth in it to be mischievous for a while. So zoologists honour their greatest! "Science," he says, has perceived "how false to natural fact the theory was." "It has shown how primordial, how organically imperative the social virtues are; how

love, not egoism, is the motive which the final history of every species justifies." And so on to some beautiful socialistic sentiment and anticipations of "the dominance of a common civic ideal, which to naturalists is known as a Symbiosis." And Prof. Geddes writes tumultuously in the same vein—a kind of pulpit science—many hopeful things of "Renascence," and the "Elixir of Life."

Now there is absolutely no justification for these sweeping assertions, this frantic hopefulness, this attempt to belittle the giants of the Natural Selection period of biological history. There is nothing in Symbiosis or in any other group of phenomena to warrant the statement that the representation of all life as a Struggle for Existence is a libel on Nature. Because some species have abandoned fighting in open order, each family for itself, as some of the larger carnivora do, for a fight in masses after the fashion of the ants, because the fungus fighting its brother fungus has armed itself with an auxiliary alga, because man instead of killing his cattle at sight preserves them against his convenience, and fights with advertisements and legal process instead of with flint instruments, is life therefore any the less a battle-field? Has anything arisen to show that the seed of the unfit need not perish, that a species may wheel into line with new conditions without the generous assistance of Death, that where the life and breeding of every individual in a species is about equally secure, a degenerative process must not inevitably supervene? As a matter of fact Natural Selection grips us more grimly than it ever did, because the doubts thrown upon the inheritance of acquired characteristics have deprived us of our trust in education as a means of redemption for decadent families. In our hearts we all wish that the case was not so, we all hate Death and his handiwork; but the business of science is not to keep up the courage of men, but to tell the truth. And biological science in the study still faces this dilemma, that the individual in a non-combatant species, if such a thing as a non-combatant species ever exist, a species, that is to say, perfectly adapted to static conditions, is, by virtue of its perfect reactions, a mechanism, and that in a species not in a state of equilibrium, a species undergoing modification, a certain painful stress must weigh upon all its imperfectly adapted individuals, and death be busy among the most imperfect. And where your animal is social, the stress is still upon the group of imperfect individuals constituting the imperfect herd or anthill, or what not—they merely suffer by wholesale instead of by retail. In brief, a static species is mechanical, an evolving species suffering—no line of escape from that *impasse* has as yet presented itself. The names of the sculptor who carves out the new forms of life are, and so far as human science goes at present they must ever be, Pain and Death. And the phenomena of degeneration rob one of any confidence that the new forms will be in any case or in a majority of cases "higher" (by any standard except present adaptation to circumstances) than the old.

Messrs. Geddes and Thomson have advanced nothing to weaken these convictions, and their attitude is altogether amazingly unscientific. Mr. Thomson talks of the Gospel of the Resurrection and "that charming girl Proserpina," and Baldur the Beautiful and Dornröschen, and hammers away at the great god Pan, inviting all and sundry to "light the Beltane fires"—apparently with the dry truths of science—"and keep the Floralia," while Prof. Geddes relies chiefly on Proserpine and the Alchemy of Life for his literary effects. Intercalated among these writings are amateurish short stories about spring, "descriptive articles" of the High School Essay type, poetry and illustrations such as we have already dealt with. In this manner is the banner of the "Scots Renascence," and "Bio-optimism" unfurled by these industrious investigators in biology. It will not appeal to science students, but to that large and important class of the community which trims its convictions to its amiable sentiments, it may appear as a very desirable mitigation of the rigour of, what Mr. Buchanan has very aptly called, the Calvinism of science. H. G. WELLS.

THE GLYPTODONT ORIGIN OF MAMMALS.

Studies in the Evolution of Animals. By E. Bonavia, M.D. (London: Constable, 1895.)

IN his preface the author writes that: "Having completed the 'Flora of the Assyrian Monuments and its Outcomes,' I was looking about for something to take up next as a subject of study. In the furriers' windows I was attracted by the leopard and tiger skins, which by degrees became objects of interesting study and speculation." In the true interests of zoology, it is to be deplored that his attention was not attracted by some other subject.

The key-note to the startling theory propounded in this volume is to be found in a sentence on page 131, where it is stated that: "The Glyptodonts, or other armoured animals of a similar nature, were the *originals* from which all existing mammals, including marsupials, descended."

This astounding statement is largely based on the belief that the rosettes on the skins of the jaguar and leopard are the remnants of the rosette-sculpture on the bony carapace of the glyptodonts, the author stating (p. 124) that these markings "are *inherited* from ancestral plate-impressions of some extinct glyptodontoid form, and have *not* been evolved by a process of natural selection."

How the author can conceive that the *Felidæ* are descended from any glyptodont-like form (by which it may be presumed an edentate is meant) will pass the comprehension of any anatomical zoologist; but all will endorse his remark (p. 163) that "one would indeed require to have lived a good bit of time to witness a Glyptodon changing into a Jaguar." This, however, is by no means all. Later on the author finds evidence of glyptodont affinities in the bosses on the skin of Rhinoceroses, and remarks (p. 217) that "the giant armadillo has its hind feet ungulate, its hoofs are almost exactly like those of the Malayan Tapir; and in some rhinoceroses the incisor teeth are wholly wanting, and that part of the jaw is contracted, not unlike that of the Glyptodon." If this means anything, it means that rhinoceroses are evolved from a veritable edentate glyptodont; and it is thus a pity the author did not enlighten us how the full dentition and claws of a jaguar were also to be derived from such a type.

It would be mere waste of space to state how mar-

supials enter the scheme, but it may be mentioned that the loss of the primeval carapace of ordinary mammals is attributed (p. 209) to a deficiency of carbonate of lime in the water and plants on which they subsisted. It will also be a surprise to zoologists to learn (p. 142) that the coloration of the Indian black-buck is due to its having lost its armour on the ventral sooner than on the dorsal surface. And equal wonderment will be experienced when they read (p. 300) that dolphins are near relatives of Plesiosaurs, and that the author doubts whether "there are any good reasons for supposing that Ichthyosaurs were *not* mammals"!

In another chapter the author is led, from the study of monstrosities, to the conclusion that horses are more nearly allied to the Artiodactyla than they are to either rhinoceroses or tapirs!

Many more similar instances might be quoted, but it will suffice to say that if the author be right, all zoologists are hopelessly in the wrong in their views on mammalian affinity.

Among the redeeming features in the book will be found many interesting observations on the coloration of cats and horses, and the author appears to have made out a fairly good case for the derivation of the striping of the tiger from the spots of a leopard-like type. Many of the figures of animals, especially the skins of leopards, are admirable examples of photography, and would be well worth reproduction in other works.

R. Lydekker.

OUR BOOK SHELF.

Le Cause Dell' Era Glaciale. By Luigi de Marchi, Libero Docente di Meteorologia nella R. Universita di Pavia. (Pavia: Fratelli Fusi.)

This work does not fulfil the expectations raised by its title. It is a prize essay of 220 large octavo pages, divided into three sections. The first treats of the climatic conditions of a glacial invasion, and here the author agrees with a number of German writers whom he quotes, in considering that a glacial epoch is due to a lowering of mean animal temperature and a diminution of the annual range, accompanied by an increased rainfall in summer. The next section treats of the temperature of the air. We find a large collection of empiric formulæ, taken for the most part from German authors, some of which are based on assumptions which appear to be far from satisfactory, and which certainly cannot be verified in the exhaustive way which one would wish before applying them to find the temperature in the Glacial Age. Among these there is one more important than the others, in which *t*, the mean annual temperature at any given locality, is expressed in terms of no less than *fifteen* physical quantities, such as the supposed temperature of an ideal sky,[1] the absolute radiating power of this sky, the transmissive powers of the atmosphere for radiation from earth and water, and for sun-heat, and last, but not least important, "a term of correction which expresses the effect of the physical and meteorological conditions of the locality," and this term may, according to the author, oscillate between −6° C. and +6° C.

The third section, entitled "The Cause of a Glacial Age," contains the author's deductions from this formula. He uses it to disprove the hypothesis that the Ice Age was due to a change in the obliquity, but he cannot apply it to discuss Croll's theory, because it only takes account of the *total* annual heat received. Hence he refers to previous writers for his criticism on Croll. Similarly the geographical hypothesis is dismissed as insufficient, so that the way is cleared for the author's own hypothesis, viz. that the Ice Age was caused by a general lowering of temperature which arose from a diminution of the atmospheric transparency, which can only be explained (p. 183) as the effect of a general diffusion into the atmosphere, over the whole surface of the earth, of a gas, vapour, or dust which absorbs, or reflects towards space, a part of the heat which comes from the sun. "But since the glacial epoch also presupposes an extraordinary rainfall, among the many hypotheses which may be framed, one spontaneously presents itself, viz. that a great mass of aqueous vapour was launched against and diffused into the atmosphere." Owing to the lowering of temperature due to want of transparency, the vapour would fall as snow, and this precipitation would go on until the mass of vapour injected into the atmosphere is entirely or in great part eliminated.

The author quotes an Italian writer, who suggests that the action of volcanos in the age preceding the Ice Ages affords a possible explanation of the (supposed) launching of these vast masses of aqueous vapour into the atmosphere.

[1] Not [illegible] temperature of space, but (following Pouillet [illegible]) the temperature of a [illegible] surface, of which the radiat- [illegible] of all the celestial [illegible] taken as equal to [illegible] C. for [illegible] the equator.

Leitfaden für histologische Untersuchungen. By Bernhard Rawitz. Second edition. (Jena: Gustav Fischer, 1895.)

Histological methods have become so perfected, microscopic appliances so modified, and staining reagents so numerous, that it is necessary to have good reference books for use in laboratories. Although there are a number of such works, amongst which we may mention Lee's "Vade Mecum," Sims Woodhead's "Manual," and Fletcher's edition of Von Kahlden's "Practical Pathological Histology," the appearance of a new edition of Rawitz's compendium will be welcomed by all who were familiar with the first edition, which was published six years ago. It resembles Von Kahlden's book in arrangement, but while this latter has been compiled specially for pathological investigations, Rawitz's "Leitfaden" is essentially intended for the biologist and physiologist, and forms a suitable supplement to its morbid counterpart. When reviewing Dr. Fletcher's translation of Von Kahlden's book, some time back, we regretted the omission of various matters relating to section-cutting, embedding and staining, an omission which is excusable on the ground that in a work on practical pathological histology a sound knowledge of these subjects might be taken for granted. Rawitz gives excellent descriptions of all our recognised modern methods, and a careful account of paraffin embedding and paraffin cutting, which will prove useful to all who wish to become familiar with what is undoubtedly the best method for general histological purposes. His directions for working with celloidin are equally good, and since this method is somewhat neglected in this country the beginner will find a number of hints which Dr. Fletcher might well have included in his translation. The completeness with which the various methods of fixation, hardening, and staining have been enumerated is admirable, and we gain the firm conviction that the author has only included what is sound, and in careful hands certain to give good and trustworthy results. Chapter xi. (part 1) contains some useful information on the art of drawing and "reconstructing" microscopical objects. The "Leitfaden" may be recommended without hesitation to the histologist as a book of reference for use in the laboratory; it will save time, and seldom cause disappointment.

A. A. K.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The University of London.

I AM anxious to make it clear that what Sir John Lubbock has sprung upon us is a radical change in the procedure of Convocation.

The object can only be, it appears to me, to obtain a reversal of its policy. As a political expedient it is, therefore, very similar to the action of those politicians who for analogous reasons would change the constitution of the House of Lords.

Sir John now defines what he calls his "suggestion" in the following words :—"That in voting on the new Charter, members of Convocation should do so 'as at a senatorial election,' *i.e.* by voting papers." I call this a radical change in the procedure of Convocation.

I put aside the not immaterial point that as a Statutory Commission is a delegation from Parliament, the result of its labours will not be embodied in a Charter, but will be virtually in effect an Act of Parliament when approved by that body.

Sir John has made the following statements about his "suggestion" :—

(1) "I am not asking that any privilege which they do not at present possess should be conferred upon my constituents, but only supporting what is now their *legal right* . . . This right I know they highly value" (NATURE, July 18, p. 269).

(2) "It is the *law* at present" (NATURE, August 8, p. 340).

The words which I have put in italics are definite and explicit, and are, of course, in flat opposition to my repeated statement that Sir John's suggestion amounts to a fundamental and, indeed, revolutionary change of procedure. This change consists in extending the mode of voting in a senatorial election to other matters. Now the mode of voting at a senatorial election is prescribed by the 21st clause of the Charter, which is printed in NATURE for July 25, p. 296. It embraces two very important points. First, the right of absent members to vote at all is not absolute but only *permissive*. The words are: "Power to the Convocation, *if it shall think fit*, to enable absent members of the Convocation to vote on such nominations . . . by voting papers." Secondly, this permissive right is strictly limited by the words "*but not so to vote on any other matter.*"

It is upon this vital discrepancy between Sir John's statements quoted above and the provisions of the Charter that I think it is imperative that he should give some explanation. This demand on my part he is pleased to call an "attack." Well, however that may be, he at least owes it to himself to meet it.

I trust, however, that I have now made it clear, and even to Sir John, that his "suggestion" is not the law, but that, further, it involves the abrogation of a portion of the Charter. I think as a member of Convocation that in making such a proposal without consulting that body he has exceeded his functions as our Parliamentary representative. At any rate it must, I think, be admitted that he is making short work of the "right" which his "constituents highly value." (NATURE, August 8, p. 340.)

I am unwilling to prolong a painful discussion. But as Sir John is pledged to bring forward his "suggestion" in Parliament, which of course can incorporate it in the Bill, if it thinks proper, it seems to me of extreme importance to dissipate his contention that it is already the "law." W. T. THISELTON-DYER.

Kew, August 23.

The Nomenclature of Colours.

THE interesting article of Mr. J. H. Pillsbury, published in your last number, recalls to me a passage in my autobiography, which, though it is already in print, will not be issued until after my death. As bearing on the question Mr. Pillsbury raises, this passage may, perhaps with advantage, be published in advance. The plan suggested aims at no such scientific nicety of discrimination or naming as that he proposes, but is one which is applicable with the means at present in use. It is, as will be perceived, based on the old theory respecting the primary colours; but whatever qualification has to be made in this, need not affect the method described. The passage is as follows :—

"I mention it here chiefly for the purpose of introducing an accompanying thought respecting the nomenclature of colours. The carrying on of such a scheme would be facilitated by some mode of specifying varieties of tints with definiteness; and my notion was that this might be done by naming them in a manner analogous to that in which the points of the compass are named. The subdivisions coming in regular order when 'boxing the compass,' as it is called, run thus :—North, north by east, north-north-east, north-east by north, north-east ; north-east by east, east-north-east, east by north, east. Applying this method to colours, there would result a series standing thus :—Red, red by blue, red-red-blue, red-blue by red, red-blue (purple) ; red-blue by blue, blue-red-blue, blue by red, blue. And in like manner would be distinguished the intermediate colours between blue and yellow and those between yellow and red. Twenty-four gradations of colour in the whole circle would thus have names ; as is shown by a diagram I have preserved. Where greater nicety was desirable, the sailor's method of specifying a half-point might be utilised—as red-red-blue, half-blue ; signifying the intermediate tint between red-red-blue and blue-red by red. Of course these names would be names of pure colours only—the primaries and their mixtures with one another ; but the method might be expanded by the use of numbers to each : 1, 2, 3, signifying proportions of added neutral tint subduing the colour, so as to produce gradations of impurity.

"Some such nomenclature would, I think, be of much service. At present, by shopmen and ladies, the names of colours are used in a chaotic manner—violet, for instance, being spoken of by them as purple, and other names being grossly misapplied. As matters stand there is really no mode of making known in words, with anything like exactness, a colour required ; and hence many impediments to transactions and many errors. In general life, too, people labour under an inability to convey true colour-conceptions of things they are describing. The system indicated would enable them to do this, were they, in the course of education, practised in the distinguishing and naming of colours. If, by drawing, there should be discipline of the eye in matters of form, so there should be an accompanying discipline of the eye in matters of colour."

Were some authoritative body to publish cards representing these various gradations of colour, arranged as are the points of the compass, each division bearing its assigned name, as above given, such cards might serve as standards ; and any one possessing them would be able to indicate, within narrow limits, to a shopkeeper or manufacturer, the tint he or she wanted. Of course to complete the method it would be needful that there should be a mode of indicating gradations of intensity, and if the numbers 1, 2, 3, were appended to indicate the degrees of impurity by mixture with neutral tint, *a*, *b*, *c*, might be used to signify the intensity or degree of dilution of the colour.

Very possibly, or even probably, this idea has occurred to others, for it is a very obvious one. HERBERT SPENCER.

The Mount, Westerham, July 23.

Clausius' Virial Theorem.

THE above-named theorem, which appeared in the *Phil. Mag.* for August 1870, much as it is now used in connection with the kinetic theory of gases, received little, if any, attention in England for some time after its introduction. Apparently the theorem was accepted without hesitation or discussion, and, as far as I can learn, neither on its first introduction or since has it received any adverse criticism, or, in fact, any criticism whatsoever. My object in writing this letter is, in the first place, to direct attention to the arguments used by Clausius to establish his theorem, which appear to me to be unsound, and secondly, by applying a simple test case, to show that the theorem itself is not true.

Clausius first proves the following equation.

$$\frac{m}{4t}\int_0^t \frac{d^2(x^2)}{dt^2}dt = \frac{m}{2t}\int_0^t x\frac{d^2x}{dt^2}dt + \frac{m}{dt}\int_0^t \left(\frac{dx}{dt}\right)^2 dt.$$

If for the moment, for the sake of simplicity, we divide bot sides of the equation by $\frac{m}{2t}$, we get

$$\tfrac{1}{2}\int_0 \frac{d^2(x^2)}{dt^2}dt = \int_0^t x\frac{d^2x}{dt^2}dt + \int_0^t \left(\frac{dx}{dt}\right)^2 dt,$$

and this may be written

$$ux = \int_0^t x\,du + \int_0^t u\,dx.$$

In this form it is easy to see that each term may be graphically represented by an area, and the equation simply expresses the fact that the rectangular area xu is equal to the algebraic sum of the areas $\int_0^t u\,dx$ and $\int_0^t x\,du$. It is obvious that for periodic motion the rectangle xu will vanish when a suitable value is given to t; but so also will the areas $\int_0^t u\,dx$ and $\int_0^t x\,du$. So that when $xu = 0$ we get, either

$$\int_0^t u\,dx = 0 \text{ and } \int_0^t x\,du = 0; \text{ or } \int_0^t u\,dx = -\int_0^t x\,du.$$

Again, in what Clausius calls "stationary motion" when xu does not vanish periodically, although we can make the expression $\frac{m}{2t}ux$ vanishingly small, by taking t very great, it is obvious that if the areas $\int_0^t u\,dx$ and $-\int_0^t x\,du$ are not equal before multiplying them by $\frac{m}{2t}$, the expressions so obtained are not so afterwards. Moreover, and finally, it should be observed that the expression $m\int_0^t u\,dx$ *does not represent kinetic energy*; to represent which the expression should be $m\int_0^t u\,du$. The above considerations seem to me to entirely upset Clausius' demonstration.

In the tenth edition of Maxwell's "Heat" (p. 323), Lord Rayleigh has given an illustration of the manner in which he supposes the "virial" to act in opposition to kinetic energy, and we may take his illustration as a simple test of the theorem. He supposes two bodies, each of mass m, to revolve in a circular path with a constant velocity about their centre of gravity. Here, as there is no pressure, the so-called virial equation takes the form

$$\Sigma\tfrac{1}{2}mv^2 = \tfrac{1}{2}\Sigma Rr.$$

In the above equation v, the velocity, is constant, and $R = mf$. If we take ρ as the radius of the circle, then $r = 2\rho$, and the equation becomes

$$\tfrac{1}{2}v^2\Sigma m = \tfrac{1}{2} \times 2\rho f\Sigma m.$$

Hence

$$\tfrac{1}{2}v^2 = \rho f;$$

which equation *does not represent the ordinary law of centrifugal force*. Lord Rayleigh omitted to notice that

$$\Sigma R = \Sigma mf = f\Sigma m = 2mf.$$

When, however, we throw overboard all ideas of "virial," and look upon the term $\frac{1}{2}\Sigma Rr$ in the so-called "virial equation" as simply representing work and equal to $\frac{3}{2}pV$, also an expression for work, then the equation

$$\Sigma\tfrac{1}{2}mv^2 = \tfrac{3}{2}pV + \tfrac{1}{2}\Sigma Rr$$

is certainly true. But there seems no possible advantage to be obtained in splitting the right-hand member into two equal terms, instead of writing the equation

$$\Sigma\tfrac{1}{2}mv^2 = 3pV\text{ ; or }\Sigma\tfrac{1}{2}mv^2 = \Sigma Rr\text{ ;}$$

in either of which forms—the first for preference—it is applicable to ideal gases. For natural permanent gases the equations become, either

$$\Sigma\tfrac{1}{2}\beta mv^2 = 3pV\text{ ; or }\Sigma\tfrac{1}{2}\beta mv^2 = \Sigma Rr,$$

and not

$$\Sigma\tfrac{1}{2}\beta mv^2 = \Sigma\beta Rr.$$

[illegible] my letter (p. 221) on "Argon and the Kinetic Theory." C. E. BASEVI.

London, W., August 14.

Incubation among the Egyptians.

ARTIFICIAL incubation, like many another practice supposed to be peculiar to modern civilisation, is but a revival from very ancient times. Diodorus, an author who wrote about forty years before the commencement of the Christian era, tells how the [illegible] of [illegible], with their own hands, bring eggs to maturity, and how the young chickens thus produced are not inferior to any [illegible] hatched by the usual means.

The process, probably with methods differing little from those of ancient times, survives to the present day among the fellahs of Egypt. In suitable places ovens are erected, and the proprietors go round the neighbouring villages collecting eggs. A sufficient number having been collected, they are placed on mats strewed with bran, in a room about 11 feet square, with a flat roof. Over this chamber, which is about 4 feet high, there is another built about 9 feet in height. The roof, which is vaulted, has a small aperture in the centre to admit light during the warm weather; below it another opening of larger dimensions communicates with the oven below. In the cold weather both are kept closed, and a lamp is kept burning within. Entrance is then obtained from the front of the lower chamber. In the upper room fires are made in troughs along the sides, and the eggs are placed on the mats below in two lines, corresponding to and immediately below the fires. The fires are lighted twice a day, the first time to die about midday, the second to last from about 3 p.m. to 8 p.m. The first batch of eggs are left for about half a day in the warmest situation, after which they are moved to make room for others, until the whole number in hand have had the benefit of the position. This is repeated for six days. Each egg is then examined by a strong light. All eggs that at this stage are clear are rejected, but those that are cloudy or opaque are restored to the oven for another four days. Then they are removed to another chamber, where there are no fires, but the air is excluded. Here they lie for five days, after which they are placed separately, about one or two inches apart, and continually turned. This last stage generally takes six or seven days. During this time a constant examination is made by placing each egg to the upper eyelid, when a warmth greater than that of the human skin is a favourable sign. The duration of the process generally extends over twenty-one days, but thin-shelled eggs often take only eighteen days. The average heat required is 86° F. Excessive heat is prejudicial. In Egypt the best time is from February 23 to April 24.

J. TYRRELL BAYLEE.

Mountain Sickness.

I HAVE just come back from a journey in the region of the Andes, and in looking over the numbers of NATURE, which had accumulated during my absence, I came across the extract, which you make in your notes of February 21, from the *Revue Scientifique*, on the subject of mountain sickness. I cannot agree with M. Kronecker's statement that beyond three thousand metres mountain sickness attacks all persons as soon as they indulge in the least muscular effort, as I made the acquaintance of many people, mostly railway men, living and working at altitudes of fourteen or fifteen thousand feet on the Oroya line and the Southern Railway of Peru, who had never experienced *soroche*, or mountain sickness. As far as my own experience goes, in three journeys across the Andes and several mountain ascents, including one to the top of the crater of the Misti, 19,300 feet above sea level, I had only one attack of *soroche*, and that was at the end of a ride on an oil engine from sea level to fourteen thousand feet in nine hours. But this was so complicated with suffocation by the oil fumes and scorching by the heat of the furnace while running through the fifty-seven tunnels on the line, that I cannot say how much was mountain sickness and how much was not. At any rate, I was perfectly well the next morning, and rode over a pass nearly seventeen thousand feet high without the slightest inconvenience. As regards the danger of a prolonged sojourn, my experience teaches me that it is almost entirely due to personal idiosyncrasy and unwise eating and drinking. A healthy person whose lungs and heart are all right, who does not over-eat and is very moderate in the use of stimulants, will not suffer from mountain sickness after the first few hours, and in many cases will not suffer at all if the ascent is sufficiently gradual. Of course very violent exertion produces distress by reason of the deficiency of oxygen. I do not think that there need be any difficulty about the officials of the proposed Jungfrau railway, if steady men, not of a full habit of body, are selected. I never heard of any trouble from mountain sickness among the Peruvian railway men unless they over-stimulated, and yet they are accustomed to go in a day from sea level to 15,764 feet on the Oroya line, and to 14,666 feet on the Southern line, and return to sea level on the following day. I may add that I have made both these journeys myself without the slightest inconvenience, and have been able to walk and ride without any trouble at the end of them.

London, August 20. GEORGE GRIFFITH.

How was Wallace led to the Discovery of Natural Selection?

THE reviewer of Osborn's "From the Greeks to Darwin" (*antea* p. 362) says that Marshall quotes the fact of Wallace's being led "to the discovery of natural selection as he lay ill of intermittent fever at Ternate," and refers one to the abridged form of the "Life and Letters of Charles Darwin" for this statement. Having only the original edition in three volumes, from the year 1887, at my disposal, wherein I cannot find it, I would draw attention to my having published the fact as far back as 1870 ("Charles Darwin and Alfred Russel Wallace. Ihre ersten Publicationen uber die Entstehung der Arten, nebst einer Skizze ihres Lebens und einem Verzeichniss ihrer Schriften." Erlangen, E. Besold, 8vo, pp. xxiii. and 56, on page xviii.) The remarks to be found there are based upon a letter of Mr. Wallace's dated November 22, 1869, and now before me, a passage of which runs thus:—

"The paper No. 9 ['on the law which has regulated the introduction of new species' A.N.H. 1855] should be read along with No. 19 ['on the tendency of varieties to depart indefinitely from the original type' P.L.S. 1858]. When I wrote it I was firmly convinced of the derivative origin of species, but had not arrived at an idea of the process. When I wrote No. 19 at Ternate [in the year 1858] I did not [know] what were Mr. Darwin's views or the nature of the work he was engaged on, except generally that it was on 'Variation.' I hit upon the idea of 'Natural Selection' (though I did not give it that name) while shivering under the cold fit of ague, and I was led to it by Malthus' views on population applied to animals. As soon as my ague fit was over I sat down, wrote out the article, copied it, and sent it off by the next post to Mr. Darwin. It was printed without my knowledge, and of course without any correction of proofs. I should, of course, like this fact to be stated."

This I did in my pamphlet of 1870 on the page quoted, and on page 39, and I hope Dr. Wallace will forgive me for now making known the whole of his highly interesting statement *in his own words*. Of course I am not sure whether he did not tell or write the same to some one else, though I am not aware that it has been published.

Ordinary mortals dream nonsense in their fits of fever, a philosopher of Dr. Wallace's standing conceives original ideas!

A. B. MEYER.

Zoological Museum, Dresden, August 19.

THE letter to Prof. Newton, published in the abridged "Life of Darwin," was written in 1887. I had entirely forgotten that I had written on the same subject to Dr. Meyer in 1869, or that he had published anything in reference to it. That letter probably contained my earliest statement on the subject, and it agrees substantially with my later statements.—A. R. WALLACE.

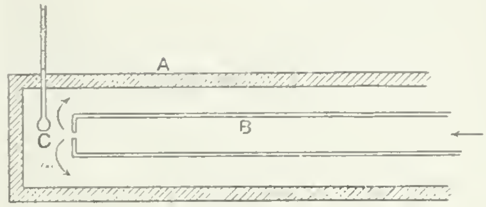
A Problem in Thermodynamics.

SIEMENS taught us how, by using the heat of the gases escaping from a furnace to heat the gas and air before entering the furnace, we could obtain temperatures limited only by the fire-resisting quality of the materials of which the furnace is constructed. Now, it occurred to me whether on the same principle very low temperatures might not be reached. My idea is this: If compressed air is expanded to atmospheric pressure, the gas does work in overcoming the resistance of the atmosphere, and is cooled to a corresponding amount.

Suppose, for instance, the gas is compressed to 1/100 of its volume, then 1 cubic metre would perform, in expanding against the atmospheric pressure of 1 kil. per 1 square centimetre, or 10,000 kilos per square metre, an amount of work equal to $10{,}000 \times 0{\cdot}99 = 9900$ kilgr.-metres, and absorb $\frac{9900}{424}$ units of heat. Now, 1 cubic metre of air weighs 1·24 kil., and, having a specific heat of 0·24, the temperature of the expanded air would be lower 78° than before expanding.

Now suppose A is a tube of a material impervious to heat—that is, a perfect non-conductor—and B a tube made of a perfect conductor of heat; the tube A being closed at one end, and B having a small opening in the end.

Now, if a continuous supply of compressed air is kept up in tube B, this air will come down in temperature, and, passing along between A and B, cools the compressed air before it expands.



I should be glad if any of your readers could give me the theoretical minimum of temperature produced at C.

Essen-Ruhr, Germany. E. BLASS.

A Remarkable Flight of Birds.

ON September 30, 1894, about 3 p.m., I was observing the sun through an 8-inch telescope. I noticed some dark figures of birds passing, like shadows, across the sun. I was using a dark glass, and the birds were, consequently, only visible when seen against the bright solar disc. The silhouettes of the birds were very sharply and clearly cut. Every few seconds a bird would emerge from the darkness, pass slowly across the sun and disappear on the other side. I watched them for over ten minutes without any decrease in their numbers. The whole number of birds must have been enormous, otherwise it would have been impossible for some of them to have passed as frequently as they did between my telescope and the sun. The birds were flying in a southerly direction, and were quite invisible to the naked eye. I was, therefore, unable to determine their distance, but should think they must have been two or three miles away, for the telescope was in focus for the birds and sun at the same time. I do not know what birds they were. Comparing the spread of their wings with the solar disc, I should say their wings subtended an angle of about two minutes. The place from which I observed them was Shere, a village between Guildford and Dorking. I am told that such a flight of birds has not before been recorded in this country, and have been urged to publish an account in the hope that other astronomers, who may have seen a similar thing, may be led to mention the fact.

Shere, Guildford. R. A. BRAY.

THE IPSWICH MEETING OF THE BRITISH ASSOCIATION.

IN our last article we gave a general outline of the local arrangements for the Meeting. The programme, as a whole, is now fairly complete. A slight alteration has been made with reference to the soirées; the first will be given by the Ipswich Scientific Society and the Suffolk Institute of Archæology jointly, and the second by the Mayor of Ipswich (Mr. J. H. Bartlet). The fitting up of the Section Rooms is proceeding rapidly, and arrangements are being made for the darkening of those in which a lantern will be used. In the case of Sections A and B, which meet in the same building, only the room allotted to Section B will be fitted up with dark blinds and a lantern screen, and the Sections will be asked to exchange rooms on days when papers requiring lantern illustration are read in Section A. The same arrangement will be made as to Sections D and K, which meet in the two rooms at the Masonic Hall. For the President's address in these Sections, the Lyceum Theatre, which is a short distance off, will be placed at the disposal of the Sectional Committees, as the Masonic Hall rooms may be hardly large enough to contain all those who would probably wish to be present on these particular occasions. For a similar reason, Section G, which meets in the Co-operative Hall, will be asked to allow the President's addresses in Sections A and B to be delivered there. A spacious room adjoining the main

street, and within two minutes' walk of the reception room, will be set apart for a ladies club-room.

The excursions will be of a more varied character than usual. On the Saturday afternoon the geologists will visit the well-known crag district, including Orford, Sudbourne, and Chillesford. This will give an opportunity for the examination in the field of many of the deposits to which the previous days' discussions have been devoted. On the same afternoon, there will be a dredging excursion down the Orwell, whilst other parties will go to Bury St. Edmunds (on the invitation of the Mayor), to Helmingham Hall, and to Southwold (where also the Mayor and a Local Committee will act as hosts). On the Thursday afternoon after the meeting, there will be another dredging expedition, and also an excursion to Colchester (on the invitation of the Mayor), to the Flint Napping Works at Brandon, and to the Broads, on which occasion the party will be entertained *en route* by the Mayor of Yarmouth. The geologists on this day will go to the Norfolk coast to examine the Glacial and Pliocene deposits in the neighbourhood of Cromer, where arrangements will be made so that those, who wish, may stay the night. Other short afternoon excursions will be made near Ipswich whenever time allows.

The programme of work in the Sections is rapidly filling up. In Section A, the President, Prof. W. M. Hicks, will take as the subject for his address, "The Fluid Theories of Ether and Matter." On the Friday a joint sitting will be held with Section B, when Prof. A. Schuster will open a discussion, in which Lord Rayleigh and Mr. Crookes are expected to take part, on the evidence to be gathered as to the simple or compound character of a gas from the constitution of its spectrum. On the same occasion, Captain W. de W. Abney and Mr. C. H. Bothamley will read papers on orthochromatic photography. There will also be important discussions in Section A, on the question of a new practical unit of heat, introduced by a paper from Mr. E. H. Griffiths, and on the objective character of combination tones, opened by Prof. Rücker. Other papers to be read in the Section will be on the teaching of geometrical drawing in schools, by Prof. O. Henrici, on the electrification and diselectrification of gases, by Lord Kelvin and Messrs. Maclean and Galt, on vertical (earth-air) electrical currents, by Prof. Rücker, on the events that go on within molecules, by Dr. Johnstone-Stoney, on the velocity of light in a rarefied gas through which a current is passing, by Messrs. Edser and Starling, on a dynamical top, by Mr. G. T. Walker, and on Boltzmann's minimum theorem, and the question of reversibility in the kinetic theory of gases, by Mr. E. P. Culverwell.

In Section B, the President, Prof. R. Meldola, will deal in his address with the relations of physiology and chemistry. The Monday will be devoted chiefly to papers dealing with the relation of chemistry to agriculture, which are already anticipated locally with considerable interest, on account of the large stake the district has in agriculture. Prof. Warington will be amongst those to read papers on the question. The Tuesday will be given up to papers on organic chemistry.

In Section C, the address of the President, Mr. Whitaker, will be devoted to the subterranean geology of the Eastern Counties, as exhibited in various deep borings and wells. Mr. Whitaker will also have a paper on the latest results in the boring for coal, now being made at Stutton. The other papers on local questions will probably deal mainly with newer Tertiary geology; Ipswich being a capital centre for the study of our Pliocene and Pleistocene deposits. Besides the local papers, communications have been promised from certain of the foreign visitors, on the correlation of our British Tertiary deposits with their continental equivalents. A paper by M. Gustave Dollfus, of Paris, on the extent of the Tertiary seas of Western Europe, will give his views of the physiography of the south and east of England in Pliocene times, and is likely to lead to some discussion. Glaciation, as was to be expected at Ipswich, will occupy a good deal of time. Prof. Sollas will exhibit the "pitch-glaciers," by which he has produced in the laboratory many of the obscurer phenomena of glaciation. Mr. Robert White communicates a paper on the glaciation of tropical South America.

Of the miscellaneous communications likely to be brought forward, we can only mention a few. Mr. Joseph Francis, the engineer to the New River Company, will have one on the method adopted to ascertain the direction of the dip in the Palæozoic rocks met with in the deep borings at Ware and Cheshunt. It may be observed that while there is no difficulty in obtaining the amount of the dip, when a solid core is brought up, it has always been a difficult problem how to obtain the far more important data as to its direction. Papers are also expected from Prof. Nicholson and Mr. Marr, on the phylogeny of the graptolites; from Messrs. Garwood and Marr, on zonal divisions of the Carboniferous system; from Mr. T. V. Holmes, on the ancient physiography of South Essex; from Messrs. Reid and Ridley, on the Arctic and Palæolithic deposits at Hoxne. Others, on American palæontology, have been promised by Profs. Claypole and Marsh.

Section D meets this year under the presidency of Prof. W. A. Herdman, and, for the first time in the history of the Association, it will be a section of zoology alone. Botany now forms a separate section, and although physiology is nominally attached to Section D for this meeting, it will in fact be unrepresented. The work of Section D will be largely devoted to questions of marine fisheries and marine zoology. On the Friday of the meeting, Prof. McIntosh will open a discussion on fishery questions, and an interesting debate is expected. Prof. Haddon will read a paper on the Royal Dublin Society's Fishery Survey; Dr. Bashford Dean, of New York, will give a paper on apparatus for catching oyster spat and its failure in practice, and will also exhibit an interesting collection of eggs and larvæ; Prof. Herdman will give an exhibition of lantern slides illustrative of fishery problems, and will explain the method of "zoning" of shores, &c., and, in conjunction with Prof. Boyce, will give a paper on oysters and typhoid. Other papers will be read by Prof. Miall, on pupation in insects; by Prof. Ritter, of New York, on budding in Tunicata; by Prof. Lloyd Morgan, on experiments on instinct in young birds; by Dr. H. O. Forbes, on the Antarctic continent, and on seals; and by Dr. Otto Maas, of Munich, Prof. Gilson, of Louvain, Prof. Howes, Mr. Moore, Mr. Hoyle, Dr. Hurst, and others on various subjects.

The following is the provisional programme for Section G:—Thursday, 12.—Address by the President, Prof. Vernon Harcourt; light railways in agricultural districts, by Major-General Webber; congelation of soil for foundation purposes, by M. Gobert; Bentley coal borings (a local work), by R. C. Rapier. Friday, 13.—The growth of the port of Harwich, by W. Birt; notes on improvement of Maas in connection with Hook of Holland route, by the President; Snowdon tram-road, by Sir Douglas Fox; notes on autumn floods of 1894, by W. H. Symons; river weirs and flood prevention, by F. G. M. Stoney. Saturday, 14.—Dredging operations at Mersey Bar, by A. G. Lyster; carbonic anhydride refrigerating machinery, by E. Hesketh; deodorising sewage by Herzite process at Ipswich, by J. Napier.—Monday, 16, will be devoted to electrical papers, among which will be the following:—Induction telegraphy, notes on further advance, by W. H. Preece; glow lamps, by W. H. Preece;

modern applications of electricity to traction, by P. Dawson; the chloride battery, by W. H. Earle; extension and development of the telephone in agricultural districts, by Major-General Webber; telephony, by A. R. Bennett; the field telegraph in Chitral campaign, by P. V. Luke; a new portable photometer, by W. H. Preece and A. P. Trotter. Tuesday, 17.—Interim report of committee on standardising; modern flour-milling machinery, by F. W. Turner; paper-making machinery, by Mr. Mason; printing without use of movable types, by J. Southward; incandescent gas lamps, by C. Cooke; B.A. Standard small screws, by R. B. Compton; uniform factor of safety in steam boilers, by J. Key.

The provisional programme for Section H is as follows:—Thursday, September 12.—Address by Prof. Flinders Petrie; skulls of the aborigines of Jamaica, by Sir W. H. Flower; skulls of the Neolithic invaders of Egypt, by Dr. J. G. Garson; Andamanese, by Morris Portman; Neolithic invaders of Egypt, by Prof. Flinders Petrie. Friday, September 13.—Worked flints from South Africa, by H. W. Seton Karr; flint and metal working in Egypt, by Prof. Flinders Petrie; flints found at Thebes, by Gen. Pitt Rivers; plateau flints of North Kent, by B. Harrison; graving tools from terrace gravels of the Thames valley, by H. Stopes; Palæolithic projectiles, by the same; megaliths of Tripoli, by Swainson Cooper; kitchen midden at Hastings (report), by W. J. Lewis Abbott. Saturday, September 14.—North-west tribes of Canada (report), by Prof. E. B. Tylor; Samoyedes of the Arctic tundras, by A. Montefiore; language illustrating primitive warfare, by Rev. Hartwell Jones; ethnographical survey (report), by E. Sidney Hartland; deviations of children (report), by Dr. Warner. Monday, September 16.—Cannibalism, by Captain Hinde; folk-lore of Ipswich, by Miss Layard; ethnographical conclusions, by G. Laurence Gomme; general conclusions, by Edward Clodd; folk-lore illustrated, by Prof. Haddon; religious origin of dances, by Mrs. Grove. Tuesday, September 17.—On interference with the civilisation of other races, by Lord Stanmore, Prof. Douglas, Prof. Haddon, and Dr. R. N. Cust, and letters of the late R. L. Stevenson; southern Arabians, by Theodore Bent; the Eskimo, by F. Linklater and J. A. Fowler. Wednesday, September 18.—Lake village of Glastonbury (report), by Dr. R. Munro; prehistoric Greek idols, by Arthur Evans; Neolithic station of Butmir, by Dr. R. Munro.

A SOUVENIR OF "CHALLENGER" WORK.

A MEDAL has been prepared as a souvenir of the scientific work connected with the *Challenger* expedition. The medal, which is in bronze, is three inches in diameter, and was modelled by Mr. Birnie Rhind, sculptor, from designs by Mr. William S. Black, both of Edinburgh. It was cast in Paris, and is being presented by Dr. John Murray to the naval officers of the expedition, the contributors of memoirs to the report on the scientific results of the expedition, and to members of the civilian scientific staff, as a souvenir of *Challenger* work.

The accompanying illustrations have been reproduced from two photographs of the casts forwarded to us by Mr. Black, and show the two sides of the medal. On the front of the medal, the head of Athena with owl occupies the centre, and is placed on the globe, which in turn is surrounded by a border of water indicating the voyage of the expedition around the world. Out of the water rises Neptune, with trident and a trawl disclosing the treasures of the deep-sea. The decoration of the border is completed with a dolphin and two mermaids supporting a ribbon with the words "Voyage of H.M.S. *Challenger*, 1872-1876."

The back of the medal bears the crest of the *Challenger*—a mailed warrior throwing down the gauntlet to Neptune, whose trident appears above the waves. This central figure is surrounded by a scroll bearing the words, "Report on the Scientific Results of the *Challenger* Expedition, 1886-1895." The name of the recipient of each medal is engraved around the edge.

It is hardly necessary to say that the medal has been very much appreciated, and appears to have been received with special satisfaction by foreign contributors to the *Challenger* Report, who regard it as a pleasing recognition of their assistance in the great work which has now been completed.

DR. FRIEDRICH W. G. SPÖRER.

IN a recent number of NATURE we unfortunately had to record the loss of an astronomer, Dr. Friedrich Tietjen, who devoted himself to computation, or, we should say, to that branch of astronomy which deals with

the methods of calculation, and with the reduction of the observations themselves.

It is our lot to-day to say a few words about another hard worker in astronomical science, whose end has followed too soon after that of Dr. Tietjen. This devoted student of astronomy has been an energetic observer in the same degree that Dr. Tietjen was an ardent computer. We refer to Dr. Friedrich Wilhelm Gustav Sporer, the former chief assistant of the Astro-Physical Observatory at Potsdam, and who died on July 7 last.

Dr. Sporer was born in Berlin on October 23, 1822, and after spending some time at the Friedrich-Wilhelms Gymnasium, he entered the University of Berlin, making mathematics and astronomy his chief studies. On December 14, 1843, he gained his doctor's degree, the subject of his thesis being the comet of 1723. In the following years he worked under Encke's direction at the Berlin Observatory, and in 1846, after having made his Staats exam., went as a teacher of mathematics and natural science to the Gymnasium at Bromberg. In 1847 he proceeded to Prenzlau, and two years later to Anclam, at which latter place he taught for twenty-five years, and became eventually Pro-rector.

It was during his leisure hours there that Dr. Sporer was able to turn his attention to astronomical observations, his instrumental equipment being of a very inferior kind. Notwithstanding this hindrance, he was able, however, by great diligence and perseverance, to make useful observations with regard to the statistics of the solar spots, which have made his name known to every worker of solar physics. Through the attention of Prof. Schellbach, who was the teacher of the then Crown Prince Friedrich Wilhelm, afterwards Kaiser Friedrich, Dr. Sporer was equipped with a good 5-inch telescope, with which he continued to make his solar observations by the known method of projection. His Anclam observations appeared from time to time in numerous articles contributed to the *Astronomischen Nachrichten*, and also in two larger papers which came out in the years 1874 and 1876 in the *Publicationen der Astronomischen Gesellschaft*. The chief value of these pieces of work lies in the careful determination of the elements of rotation of the sun, and also in the more accurate settlement of the then empirically known law of Carrington, namely, the decrease in the velocity of rotation of the sun-spots according to increase of solar latitude.

In the year 1868, accompanied by Prof. Tietjen and Dr. Engelmann, Dr. Sporer took part in the astronomical expedition to observe the total eclipse of the sun visible in the East Indies. Six years later (1874) he received the appointment as observer at the Potsdam Astro-Physical Observatory, and in the same year continued his solar observations from the top of the tower of the Military Orphan Asylum, until the completion of the observatory.

Here Dr. Sporer, with untiring energy and with the same ardour that he displayed in Anclam, did a great amount of work in collecting data on the subject of sun-spots. The publications of the Astro-Physical Observatory (years 1879–1894) contain four valuable papers by him, giving a rich quantity of accurate observations that will remain a classical work for the study of the proper motion of the solar spots.

In 1882 Dr. Sporer became chief assistant, and this position he held until October 1894, when he retired for a well-earned rest.

From Dr. Sporer's observations of solar spots, the most important deductions that have been made may be summed up as follows:—

(1) That the period of rotation of the apparent surface of the sun about its axis, is not the same for every part.

(2) That the velocity of the spots is greater nearer the equator than further away from it, and that this velocity can be approximately represented by a formula.

(3) That the variation in latitude is periodical, and that there are two series of spots. We learn thus that the true sun-spot cycle is one extending over twelve to fourteen years, and that another begins in high latitudes before the former has ceased.

(4) His observations of the quantity of spotted area between the years 1856–1880, show a length of period of eleven years, this being the time between two consecutive maxima.

The maximum is reached when the mean latitude of the spots is about 16° north and south. A retreat then takes place from about 30° to 16°, that is, 14° in four years, and a further retreat from 16° to 8°, that is, 8° in eight years; or, in other words, we get a change of latitude of over 3° a year to begin with, and one of $\frac{1}{2}$° a year to end with.

Such results as these, which have here only been briefly summarised, are of fundamental importance, and form valuable data for those attempting to investigate the conditions of atmospheric circulation at the surface of our sun. Since the observations have been made consecutively by such a diligent observer, and extend over a considerable period of time, they are strictly of a uniform nature, and in consequence they are comparable *inter se*.

Happy in his work, and endowed with a strong constitution, Dr. Spörer was free from the ailings of old age up to his last day. It was when on a journey to visit his children that he was suddenly seized with paralysis of the heart, without ever having had any previous sign of illness, and died quietly and without pain.

His loss not only affects the astronomical world, but his large circle of friends, all of whom will mourn deeply such a sudden and unexpected bereavement.

W. J. S. L.

NOTES.

Considerable activity has been displayed at the Plymouth laboratory of the Marine Biological Association during the present summer, and general satisfaction has been experienced by the naturalists who have visited the station for the purpose of research. Progress has been made with the series of dredging operations in the outlying grounds of the neighbourhood. The unsettled weather of the past two months has been a somewhat unfavourable condition in these expeditions; but it is expected that these operations may be carried on regularly and with increased success during the autumn months. The following naturalists have occupied tables at the laboratory during the summer: Prof. Weldon, F.R.S., Mr. G. P. Bidder, Mr. W. Garstang, Mr. T. H. Riches, Dr. Albrecht Bethe, Mr. W. J. Beaumont, Mr. Gilchrist, and others.

A well-marked earthquake disturbance was felt at Zermatt on Wednesday, August 21. Many houses were severely shaken.

Among the deaths of eminent scientific men abroad, we notice the name of Dr. F. Hoppe-Seyler, professor of physiological chemistry in Strassburg University, and also that of Dr. S. Moos, professor of otology in Heidelberg University.

We regret to record the death of Dr. J. S. Bristowe, F.R.S., whose work on the "Theory and Practice of Medicine" is recognised as a classic, while his other contributions to scientific literature give him a high place among medical worthies. Dr. Bristowe had filled the offices of President of the Medical Society, of the Pathological Society, and of the Neurological Society. He was elected into the Royal Society in June 1881.

THE Assistant Clerk to the Geological Society, Mr. F. E. Brown, died suddenly on Sunday, August 4. The Society loses in him an invaluable official, who was ever rigid in the exact performance of all his duties, and combined with strict business-like habits a courtesy and patience which endeared him to his colleagues and to the Fellows generally.

THE eleventh Congress of Americanists will be held in the City of Mexico, on October 15-20. The meeting has for its principal object the progress of ethnographical, linguistic, and historical studies of the two Americas, especially with reference to the period prior to the discovery of the New World. Among the matters which will be discussed at the forthcoming gathering are the following:—The relations existing between different American peoples before the discovery; maps of the Atlantic and Pacific Oceans in the sixteenth century; medical natural history of the Ancient Mexicans; public instruction in Mexico in early times, and from the conquest of Mexico to the middle of the sixteenth century; mines and metallurgy before the conquest of Mexico; interpretation of the symbolic dances of the Azetics; different forms of arrows and their use among the natives of Central America; recent researches with regard to the first appearance of man in America; relationships between the Esquimaux and other native races of North America; prehistoric man in Mexico; the stone carvings in Central America; the pottery of Nicaragua and Costa Rica; the chronological classification of the monuments of Mexico and Central America; the human inhabitants of caves and grottos; Indian hieroglyphics; names of animals in the native languages of Central America; the decipherment and comparison of the hieroglyphics of ancient races of Mexico; the use of hieroglyphic writing since the conquest of Mexico, and the importance of its study in connection with the Mexican and Mayan languages. The President of the Congress is Sr. J. Baranda, and the Secretary, Sr. T. S. Santos, to whom all memoirs and other communications should be addressed at the Bibliothèque Nationale, Mexico.

DURING the latter part of last week the area of high barometric pressure that had prevailed over the greater part of the British Islands gave way to small disturbances, which either approached from the Atlantic, or were formed immediately over this country, causing severe thunderstorms over England and Ireland, while lightning was also visible in Scotland. In the storm of Thursday night (22nd inst.) the lightning was extremely brilliant in London, the flashes during part of the time being almost continuous. Considerable quantities of rain fell in many localities, and in some of the English districts much damage was done by hail.

THE problem solved by Edison's kinetoscope has been successfully attacked along a different line by MM. A. and L. Lumière. The film which in the kinetoscope takes the impressions of moving objects is passed before the eye with a continuous motion, and it is only illuminated for about a 7000th of a second at the instant at which each successive picture is fully in view. Hence the total illumination is exceedingly feeble. A very bright object is necessary; the eye has to be brought close to the moving film, and the number of impressions per second must be at least thirty in order to give continuity. MM. Lumière's "kinematograph," which is not subject to these disadvantages, is described in the *Revue Générale des Sciences*. The principal features of this instrument are a mechanism whereby the film is at rest during illumination, and an arrangement for projecting the images upon a screen, so as to be visible to a large meeting. Under these circumstances, fifteen images per second are all that is necessary. The film is at rest for two-thirds of the time of passage of each image. During the remaining third the film is grasped and pulled forward as far as the next image by a set of teeth attached to a frame whose motion is governed by a cam worked by a revolving handle. The same apparatus also serves as a camera for taking the photographs, and for printing transparencies from the negative film. For this purpose two films are passed over the rollers, the negative and the film to be printed on, and exposure is made for a very short time as each negative image is placed in the field. An exhibition was given on July 11, at the offices of the *Revue Générale des Sciences*, at which the evolutions of cuirassiers, a house on fire, a factory, street scenes, and a dinner-party were shown on the screen, and were much admired.

A NUMBER of observations referring to a shower of dust in connection with snow in Indiana and Kentucky, are brought together and discussed in the *Monthly Weather Review*. The dust does not appear to have been the nuclei of snowflakes, but was intermingled in the air with the snow, and fell during an interval between two snow-storms. An examination of numerous samples showed that the dust was made up largely of silt, mixed with organic matter. A number of freshwater algæ were distinguished, though they appear to have been dead and dried for some time. There were also groups of diatoms, fungi, animal and plant hairs, fibres of grasses, shreds of woody tissue of some shrub or tree, and many other objects in the samples examined. Everything indicated that the material came from the bottom of some dried-up lake, pond, or marsh, or some river-bottom. To afford information upon the belief that this fine material is very valuable as a fertiliser, an examination of the dust was made from that point of view. The analyses showed that the material is no better fertiliser than any other good surface soil. The dust was almost identical with the so-called "loess" formation, which covers very extensive areas in Illinois, Indiana, Nebraska, and other adjoining States; its depth in some places amounting to a hundred feet or more. This is interesting, because there is a long-standing controversy as to the origin of the loess formation of the North-west. Certain portions of the loess formation of Asia are known to be wind deposits, and there is very strong presumptive evidence, now borne out by the examination of the samples of dust, that much of the loess of the Western States is also a wind deposit. Special interest is thus attached to the dust-storm referred to, on account of the bearing of the observations on the question of the formation of agricultural soils, and especially the loess, which is the lightest and finest of all. This light soil is easily raised and carried by the strong winds of the western plains of America; instances have occurred in which six inches of surface soil have been blown away from freshly cultivated fields in the course of a single wind-storm. Prof. Cleveland Abbe is of the opinion that the dust caught between the two layers of snow in Indiana, probably did not differ materially from that which is daily present in the atmosphere of that region, but its presence on the top of a layer of snow rendered it easy to gather the dust-fall without contamination with the soil already existing. So this dust formation, or loess, when it has once settled upon the ordinary soils, becomes a new ingredient in their composition, and is therefore well worth further study.

A USEFUL bulletin, on the pasteurisation of milk and cream for direct consumption, has been issued from the Agricultural Experiment Station of the University of Wisconsin. It is drawn up by Dr. H. L. Russell, the bacteriologist attached to the station, and contains much interesting matter. There can be no doubt whatever that the pasteurisation of milk is a most important hygienic measure, destroying as it does an average of about 99·7 per cent of the microbes present in milk, amongst which are the diphtheria and typhoid microbes, as well as those organisms associated with gastric and intestinal disturbances so common in young infants during the summer. It is claimed

that the introduction of pasteurised milk among the poor people of New York, through the philanthropic efforts of Mr. Nathan Straus, has done much to reduce the infant mortality in that city during the hot summer months. The practical side of the question has not been lost sight of by Dr. Russell, and the results of his experiments on the efficient production and distribution of pasteurised milk on a commercial scale are carefully brought together. The subject is one of great importance, both from a hygienic as well as commercial point of view, and we may surely hope that before long our dairy authorities will take the matter up, and that we shall follow, though tardily, the example already set us by our neighbours in France and Germany, where pasteurised milk may be purchased across the counter.

THE volume of "British Rainfall" for 1894, compiled by Mr. G. J. Symons and Mr. H. Sowerby Wallis, from observations made at more than three thousand stations in the British Isles, has just been published. As in previous years, the volume contains articles upon various branches of rainfall work, and upon rainfalls of exceptional interest.

DR. TH. WOLF has contributed to the *Verhandlungen der Gesellschaft fur Erdkunde zu Berlin* (Bd. xxii. Nos. 4 and 5, 1895, pp. 246–265, pl. iii.) a detailed sketch of the Galapagos Islands, describing their geology, in some detail, with shorter accounts of the botany and zoology. He denies that there are any grounds for Dr. Baur's theory that the islands were once connected with the mainland of South America.

WE have on our table the *Journal* of the Royal Agricultural and Commercial Society of British Guiana, containing two papers of scientific interest, viz. "Cane Cultivation in the Straits Settlements," by Mr. F. Campen, and "A Journey to the Summit of Roraima," by Mr. J. J. Quelch; also the *Journal* of the Institute of Jamaica, which, though mostly taken up with matters of historical interest, contains several notes on local natural history topics, and a note on the discovery of aboriginal Indian remains in the Port Royal Mountains, already described in these columns by Mr. J. E. Duerden (p. 173).

THE report of the Royal Prussian Meteorological Institute for the year 1894 draws attention to two points: the completion of the arrangements for magnetic observations at the Potsdam Observatory, and the conclusion of a number of balloon ascents made during the year. The results of these ascents will be made the subject of a special investigation; one of the balloons, sent up with registering instruments only, reached an altitude of over sixty thousand feet. The report shows that many important publications have been issued, both officially, and in various periodicals, by members of the staff; some of these papers have been noticed in our columns. The laboratory experiments carried on by the Institute are of a high order, and have attracted the attention of scientific men in various countries.

THE Royal Horticultural Society's *Journal* for August has in it several important papers. There is a report of the Primula Conference, held a short time back with the idea of increasing and improving the culture of the various species of Primula by procuring new plants from remote regions; by practising the most successful methods of culture; and by producing hybrids. A paper on the botanical work done on the genus Primula since the last conference in 1886 was contributed by Mr. J. G. Baker, F.R.S., and this is printed with one on the culture and classification of Primulas, by Mr. H. Selfe-Leonard, and another on the Auricula, by Mr. J. Douglas. Among the other papers in the *Journal*, we notice a long and very valuable description of the plants and gardens of the Canary Isles, by Dr. Morris, C.M.G., and a paper on the culture of roses under glass, by Mr. F. Cant.

DR. K. SAPPER has supplemented his recent memoir, "Bemerkungen über die raümliche Verteilung und morphologischen Eigentümlichkeiten der Vulkane Guatemalas" (*Zeit. deut. geol. Ges.*, Bd. xlv. 1893), by a further account of the topography of some of the less-known volcanos. (*Petermann's Mitth.* Bd. xli. No. 5, 1895, pp. 105–109, pl. vii.) In spite of the fact that the volcanos of Guatemala have been repeatedly examined during the last half-century, and described in Dollfus and Montserrat's classical work, many of them were almost unknown. Dr. Sapper now describes the volcanos of Acatenango, 3950 m., which consists of five craters in line; San Pedro, 3050m., on which no trace of recent volcanic action remains, for the mountain is wooded to the summit, and the crater has been destroyed; and a group of western volcanos. He was anxious to explore the previously unknown Lacandon, which if proved to be volcanic would fill up a gap in the chain. He was unable to ascend the mountain, but saw sufficient to render it almost certain that Lacandon is a volcano of the first order.

THE Madras Government Museum is, to judge from the Administration Report for the year 1894–95, a very progressive institution. Mr. Edgar Thurston, the superintendent, appears to be sparing no efforts to make the museum more valuable for educational purposes, and for reference in connection with natural history, economic, and other subjects, and also more attractive to the ordinary sight-seer. The increase in the number of visitors to the museum during the year—from 311,112 to 368,282—shows that his efforts are appreciated. We notice with interest, that an entirely new departure was made, during the year covered by the report, by the commencement of a detailed anthropological survey of the races, castes, and tribes which inhabit Southern India. The Madras Government express in the report their satisfaction that the survey has been set on foot. Mr. Thurston has already collected sufficient evidence to make it clear that his investigation will prove of great interest and value.

WHEN Mr. Alfred Daniell's "Text-Book of the Principles of Physics" (Macmillan) appeared, eleven years ago, it was at once hailed as an original work, and a decided acquisition to the literature of physics. The third edition, which is now before us, maintains the characteristics of the original issue. At the time when the work was designed, it was possible for a medical student to obtain the degree of Doctor of Medicine without any adequate knowledge of physics. "That arrangement," Mr. Daniell then wrote, "is self-evidently opposed to common-sense, and to the exigencies of physiological study and of medical practice; such an anomaly cannot, it may be anticipated, endure much longer. Before many years are over, it will be universally acknowledged in practice, as it already is in theory, that knowledge of natural philosophy is an essential part of the mental equipment of the medical student and of the properly-trained medical man." It is satisfactory to be able to record that Mr. Daniell's prognostication was fulfilled in 1892, when the new regulations of the General Medical Council came into force, and it is also gratifying to know that medicine is every day becoming more truly scientific in its methods and objects. Mr. Daniell's work is by no means only suited for a medical class-room; it is alike useful to all students of science. The leading principles of physical science are set forth in the pages of the book in language the precision and accuracy of which make the volume welcome to all who study physics.

WE have received from the Deutsche Seewarte the first supplement to the principal catalogue of its valuable library, which now contains some seventeen thousand works relating to meteoro-

logical and kindred sciences, and includes the important collection of the late Prof. H. Dove. It is arranged under subjects, with the titles under each entered according to authors or institutions, while an alphabetical index at the end facilitates the reference to the subject catalogue. Opinions differ as to the best method of publishing such a work, the strictly alphabetical arrangement, such as followed by Prof. G. Hellmann in his excellent *Repertorium der Deutschen Meteorologie*, or the Royal Society's catalogue of scientific papers, possesses great advantages, and obviates the necessity of indexing one book under several sections; but as the Seewarte originally adopted another method, it has perhaps done well to keep to the same plan, and has rendered good service to science by its careful preparation and timely publication of the catalogue. The first part was issued in the year 1890.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Mr. Hugh H. Collis; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. E. Laundy; a Vervet Monkey (*Cercopithecus lalandii*, ♀) from South Africa, presented by Mrs. Edward Webb; two Brown Capuchins (*Cebus fatuellus*) from Guiana, presented by Major W. S. D. Liardet; two Black-eared Marmosets (*Hapale penicillata*) from South-east Brazil, presented by Mrs. H. V. Friend; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Mr. J. Lewis; a Purple-capped Lory (*Lorius domicella*) from Moluccas, presented by Mr. T. Bailey; two Tarantula Spiders (*Mygale*, sp. inc.) from Trinidad, presented by Mr. J. Hoadley; six Grey Parrots (*Psittacus erithacus*) from West Africa, deposited; a Collared Fruit Bat (*Cynonycteris collaris*), a Ypecha Rail (*Aramides ypecaha*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

REAPPEARANCE OF SWIFT'S COMET.—The *Edinburgh Circular*, No. 44, publishes a telegram from Kiel announcing that Comet Swift was seen by Mr. E. E. Barnard, at the Lick Observatory, on the 20th and 21st inst. The comet is described as faint, and its position and daily motion are given as follows:—

Local Mean Time.	R.A.	Decl.
h. m.	h. m. s.	° ′ ″
1895, August 21, 11 23·7 ...	0 30 11·4. ...	+5 38 55
Daily Motion ...	+2 48 ...	+ 10

THE LATITUDE VARIATION TIDE.—One of the most interesting outcomes of the recognition of the variability of the earth's axis of rotation has been the search for the tide, corresponding to the latitude variation. The separation of the axis of rotation from the axis of figure must cause at any point on the earth's surface successive divergences of the sea-level, from that which would exist if the figure of the earth remained a fixed ellipsoid of revolution. This consideration naturally led to the inquiry whether a small oscillation in the mean sea-level could be actually detected, having the same period as the displacement of the pole. The earliest results published were those obtained by Dr. Bakhuyzen (*Astr. Nach.* No. 3261), who used the tidal observations for the years 1855 to 1892, registered on a mareograph at the Helder, and these results showed a satisfactory agreement with those deduced from astronomical observations.

In the meantime Mr. A. S. Christie has been at work on the records made at the United States Coast Survey mareograph stations, and his results, embodied in a paper read before the Philosophical Society of Washington, are now before us. The paper is divided into two sections, the first of which is devoted to the derivation of the formulæ necessary for the elimination of the effects of other tides, and the second contains the results of the application of these formulæ.

The observations employed are obtained from two series, made at stations in the vicinity of San Francisco, namely, at Fort Point (1856–70) and Sausalito (1877–91). Mr. Christie has also used a similar series made at Pulpit Harbour, Penobscot Bay, Maine (1870–88). It will be sufficient to give here the final result arrived at by combining the results at San Francisco and Pulpit Harbour. The period deduced is 431 ± 4 days, and the value of the half-range tide is 15 ± 2 mm.; while the dates at which the critical phases of the tide occurred are:—

	San Francisco.	Pulpit Harbour.
Min.,	1872, July 15 ± 15 days ...	1878, August 22 ± 10 days.
Max.,	1873, Feb. 15 ± 15 ,, ...	1879, March 25 ± 10 ,,

Dr. Bakhuyzen's value of the half-range is 8·2 mm., a result that does not differ greatly from the mean here given, 15 mm., or from either of the two results, 17·4 mm. and 12·5 mm., on which this value rests.

Reduced to the latitude of Berlin, we have another comparison between the investigations of the American and Dutch astronomers, and the results are still fairly satisfactory, as shown below:—

Julian Date of Maximum Latitude of Berlin.

Bakhuyzen,	from astronomical observations	2405141 Julian
,,	from discussion of Helder tides ...	201
Christie,	from San Francisco tides	153 ± 16

It seems possible, therefore, that this difficult question of the motion of the earth's pole may be attacked by two quite separate processes.

THE SOLAR PARALLAX FROM MARS OBSERVATIONS.—With the view of making a new and trustworthy determination of the solar parallax, a scheme was suggested in 1892 by the authorities of the Washington Observatory for the observation of the difference of declination at the time of meridian passage between Mars and a number of selected stars. The horizontal equatorial parallax of Mars reached in that year a maximum of 23″·4, a sufficiently favourable condition, though the small altitude of the planet in the northern observatories was likely to introduce considerable uncertainty in the amount of refraction. Among the observatories that replied to the invitation of Washington to take part in this scheme are those of Gotha and the Cape of Good Hope. The result of the combination of the two sets of observations has recently been published by Dr. Paul Harzer, and are of especial interest, since Gotha lies nearly on the northern limit of the region in which observations of Mars could be made with sufficient accuracy.

It was a part of the original suggestion—to which some exception was taken at the time—that in addition to the method of fixing the declination of the centre of Mars by the employment of a pair of wires, separated by about 16″ to cut off equal segments from the northern and southern limbs of the disc, a reflecting prism should be mounted outside the eyepiece, and that half the observations should be made with, and half without the use of this additional apparatus. The result of the precaution is shown in the following figures, in the case of the two observers who took part in the series:—

	Dr. Harzer.	Dr. Rohrbach.
Mars stars ...	+0″·253 ± 0·039 ...	−0·383 ± 0·129
Mars	−0·270 ± 0·091 ...	−0·523 ± 0·262

These figures imply that Dr. Harzer placed the stars too low and the planet too high with reference to the threads, Dr. Rohrbach, in both cases, too high.

The observations were continued from June 22 to September 23, and when combined in three groups, formed on the assumption that the error of the ephemeris is constant throughout each group, the resulting values of the solar parallax are—

Group I.	...	$\pi = 8''\cdot680 \pm 0\cdot081$
,, II.	...	$= 8\cdot890 \pm 0\cdot089$
,, III.	...	$= 8\cdot828 \pm 0\cdot065$

or combined into one, $\pi = 8''\cdot799 \pm 0''\cdot044$.

The complete combination of the whole series formed into 20 normal places, and in which the possible variation of the error of the ephemeris is also sought, gives $\pi = 8''\cdot800 \pm 0''\cdot039$, and the value of $d\delta$ is expressed in the form

$$d\delta = \frac{-1''\cdot147 + 0''\cdot288t}{\Delta},$$

where t and Δ are reckoned from August 7·000, and the unit for t is 50 days.

THE SUN'S PLACE IN NATURE.[1]

X.

The New Classification of the Stars.

I NOW pass to the new classification of stars which has been suggested by the totality of the facts which I have so far brought before you.

Although the first observations of stellar spectra were made by Fraunhofer, we owe to Rutherfurd the first attempt at classification. In December 1862 he wrote as follows:[2]

"The star spectra present such varieties that it is difficult to point out any mode of classification. For the present I divide them into three groups. First, those having many lines and bands and most nearly resembling the Sun, viz. Capella, β Geminorum, α Orionis, Aldebaran, γ Leonis, Arcturus, and β Pegasi. These are all reddish or golden stars. The second group, of which Sirius is the type, presents spectra wholly unlike that of the Sun, and are white stars. The third group, comprising α Virginis, Rigel, &c., are also white stars, but show no lines; perhaps they contain no mineral substance, or are incandescent without flame.

"It is not my intention to hazard any conjecture based upon the foregoing observations; this is more properly the province of the chemist, and a great accumulation of accurate data should be obtained before making the daring attempt to proclaim any of the constituent elements of the stars."

This classification was followed up by Secchi, who practically adopted Rutherfurd's three groups, changing, however, the word group to type, and adding a fourth. On this point Dr. Gould, in his memoir[3] of Rutherfurd, writes as follows:

"I cannot forbear calling attention to the classification, [illegible] the same, subsequently published by Secchi without reference to this or to any of the other labours of Rutherfurd, and which is generally cited under Secchi's name." (See "[illegible]," p. 258, and "Translation," pp. 235 236.)

In [illegible] other subsequent classifications—and of course [illegible] our stars if we are to speak about them with [illegible], and to understand the relations of one body or [illegible] to another—it has been taken for granted that [illegible] whatever to do with stars, and that all the stars lie along one line of temperature, the highest temperature being at one end, and the lowest at the other. Such, at all events, is Vogel's view. Now we have to conclude that nebulæ are stars to be, and that some apparent stars are really nebulæ; and I think I have shown you sufficient justification for the idea that the undisturbed nebulæ are of relatively low temperature; hence we have bodies getting hotter as well as bodies getting cooler, and both must be provided for.

In 1873 Dr. Vogel brought out a new and much more detailed classification considerably extending the number of groupings employed by Rutherfurd and Secchi. This classification is based on the assumption that all stars began by being very hot, and that the various changes observed in the spectra are due to cooling,[1] and the presence of bright lines is considered as a matter of secondary importance only, and gives rise to sub-groupings only.

Dr. Scheiner has quite recently accepted this statement. He appeals to his new observations of the spectrum of magnesium as a "direct proof of the correctness of the physical interpretation of Vogel's spectral classes, according to which Class II. is developed by cooling from I., and III. by a further process of cooling from II." (*Astronomy and Astro-Physics*, 1894, p. 571.)

Pechüle was the first to object to Vogel's classification, mainly on the ground that Secchi's types 3 and 4 had been improperly brought together.[2] Now the views I have brought before you cut at the root of such a classification as this.

It is perhaps worth while in passing to point out that in the course of lectures I gave here in 1880 I stated, taking the then classification as a basis[4]:

"On the nebular hypothesis, supposing . . . that we started with ordinary cometary materials, then, on the beginning of a central condensation which in time is to become a star, as Kant and Laplace suggested, such central condensation should then give us a star of the fourth class. As the energy of condensation increased and the temperature got higher, the spectra would change through the third and second classes, till ultimately, *when the temperature was highest*, the first class spectrum would be reached. *On the slackening down of the temperature* of the now formed star, the spectra of the second, third, and fourth classes would then be reproduced, but, of course, now in the direct order."

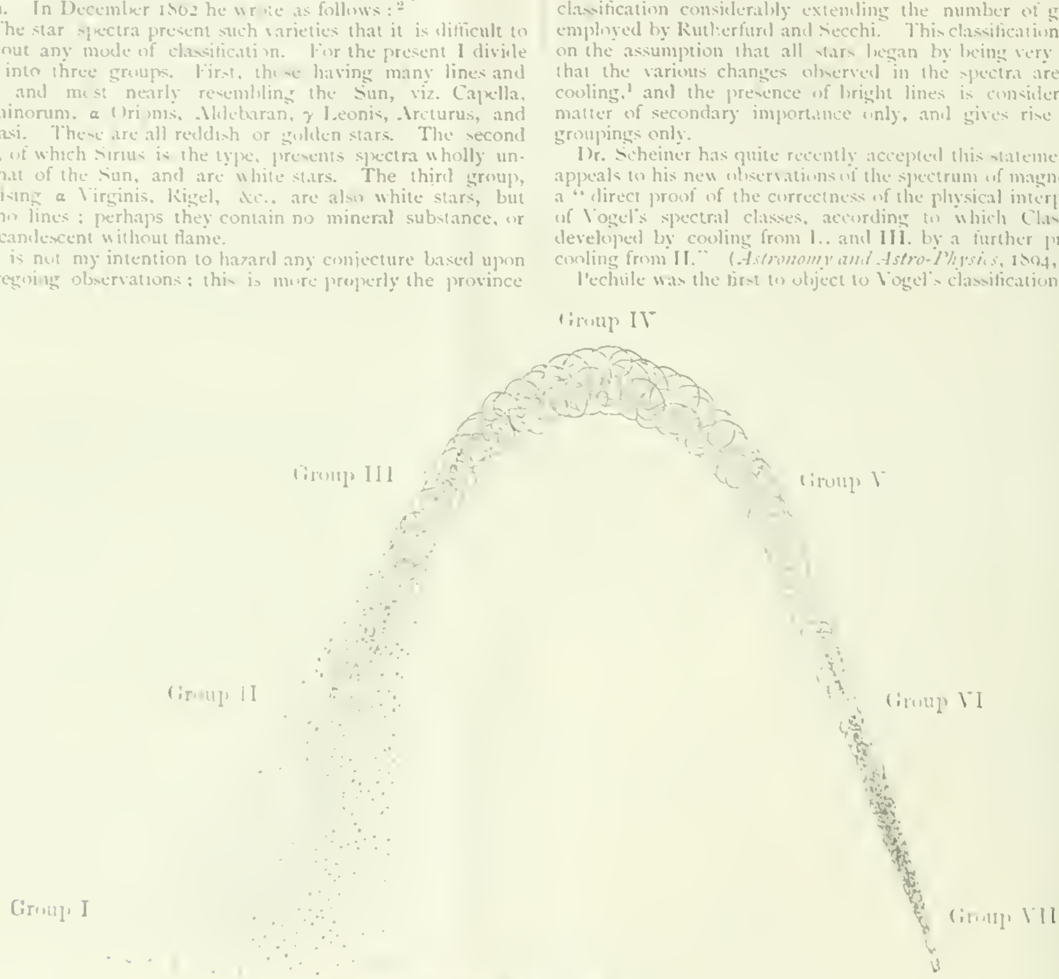


Fig. [illegible]. Temperature curve.

[1] [illegible] to Working Men [illegible] November and December, 1894 [illegible]

[2] [illegible]

[3] [illegible]

[1] "Selon [illegible] de la première [illegible]." Duner.

[2] [illegible] are given in my "Meteoritic Hypothesis," pp. [illegible]

[4] Lockyer, Nature, vol. xxxiv. [illegible]

We now know that this classification will not do, since all reference to bright lines is omitted, and every one now agrees that they must take the first place, and this is one of the great teachings of the views I have been bringing forward for the last ten years.

The idea which one arrives at by a discussion of all the spectroscopic facts is that we begin with a condition in which meteorites in swarms and streams are very far apart, and we get from the collisions of these a spectrum which gives us bright flutings and lines, in other words the spectrum of the nebulæ; when they get a little more dense, we get the bright-line stars: and as they get still more dense, we find the star with a mixture of bright and dark flutings. Then we get still more condensation and dark lines, and then the highest temperature of all; after which begins a descent on the other side, till at last we end in cool, dark bodies like the earth and moon.

This seems to be the classification which is necessitated by the consideration of all the facts, and it is, moreover, one which seems to give us possibilities of an explanation of the phenomena of new stars and variable stars, and many other things without going into the region of the unknown and impossible.

It also lands us in the so-called temperature curve along which I ventured to place the various classes of nebulæ and stars some time ago. I am glad to say that so far no valid objection has been made to it.

It will be noticed that in the classification I have suggested I use the word "group," first employed by Rutherfurd; it is one which ought never to have been changed.

With regard to this subject, Prof. Keeler, one of our most important authorities in this matter, agrees that a classification which depends on this temperature curve certainly has advantages over other systems. He writes [1]:—

"Prof. Lockyer's system of stellar classification provides for both an ascending and a descending branch of the temperature curve, and in this respect it certainly has advantages over other systems which claim to have a rational basis."

I am also more glad than I can say that Prof. Pickering, who has now given many years, with the aid of appliances beyond all precedent, to the study of these questions, has arrived at conclusions strikingly similar to my own.

In the first place he includes the nebulæ as well as the stars in his system: but it is right that I should add that he does not commit himself to any statements relating to the relative temperature of the different groups, although he distinctly accepts the idea of evolution, or what he terms an order of growth.

He writes (*Astronomy and Astro-Physics*, 1893, p. 722):

"In general, it may be stated that, with a few exceptions, all the stars may be arranged in a sequence, beginning with the planetary nebulæ, passing through the bright-line stars to the Orion stars, thence to the first type stars, and by insensible changes to the second and third type stars. The evidence that the same plan governs the construction of all parts of the visible universe is thus conclusive."

Prof. Pickering's results may be shown in tabular form, but first it will be well to show the general differences between the more recent classifications:

	Secchi.	Vogel.	Lockyer.
Nebulæ	Not classified.	Not classified.	Group I.
Bright-line stars ...	,,	,,	
Mixed fluting stars ..	Type III.	Class III*a*.	,, II.
Dark line stars (ascending)	,, II.	,, II.	,, III.
Broad hydrogen stars ...	,, I.	,, I.	,, IV.
Solar stars	,, II.	,, II.	,, V.
Carbon absorption stars...	,, IV.	,, III*b*.	,, VI.

In his classification, Prof. Pickering begins with the earliest stages, taking the planetary nebulæ and such nebulæ as that of Orion; he then comes to the bright-line stars, and then to such stars as those of Orion, and ultimately places the Sun, as I also do, after the spectrum of such a star as Sirius. There are practically two departures in his classification from that given by myself. One is that what I call the bright and dark fluting group of stars, represented by several of the red, and brightest, stars in the heavens, he makes cooler than the Sun. And the class of stars which I group together and call Group VI., in which we get mainly the absorption of carbon in the atmosphere, he omits altogether, possibly for a very wise reason, as they are certainly the most difficult stars to tackle; but you see the divergences in his classification from mine are small as compared with those between Dr. Vogel and myself, and he, I repeat, like myself, attributes the variation to an "order of growth."

[1] *Astronomy and Astro-Physics*, 1894, p. 60.

This premised, the differences of sequence between Prof. Pickering and myself may be shown as follows:

Lockyer.	Pickering.
I.	I.
II.	
III.	III.
IV.	IV.
V.	V.
VI.	II.

Prof. Pickering, in the Draper Catalogue, combines like stars under the different letters of the alphabet. The distribution of these letters in relation to my Groups is as follows:—

	Lockyer.	Pickering. (Draper catalogue.)
Nebulæ	I.	P. (Planetary Nebulæ.)
Bright-line stars...		O.
Mixed fluting stars	II.	M.
Dark-line stars (ascending) ...	III.	B. H. I. K. (?)
Broad hydrogen stars	IV.	A.
Solar stars	V.	F. G. K. L.
Carbon absorption stars ...	VI.	N.

It will be seen that certain groups are represented by more than one letter, but it is to be noted that here again Prof. Pickering and myself have arrived at very nearly similar results, for generally a different letter with him represents a sub-group with me. This will be gathered from the subjoined table.

Table showing the subdivisions of Groups III. and V.

Group.	Pickering.
III. α	H.
III. β	I. (some Q.)
III. γ	B.
V. α	F.
V. β	G.
V. γ	K. L.

With regard to Prof. Pickering, then, I have chiefly to justify the place I have given to the stars of my Group II., which I place after the nebulæ and bright-line stars, and he places after the Sun.

I fancy that one of the reasons which has led Prof. Pickering to this conclusion is to be found in the assumption that strong indications of calcium and iron can only mark one stage of growth, while I think it is certain they must mark two.

We know they mark the present stage of the Sun's history, and taking meteorites as we find them, a relatively low temperature would provide us with more calcium and iron vapours to act as absorbers round each one than anything else.

Now we have strong indications of calcium and iron absorption in such stars as α Herculis as well as in the Sun, but the general appearance of the spectra of these stars is so different that both Secchi and Vogel have classified them apart, and so indeed does Prof. Pickering.

But the reason that I classified these stars also in different groups, and one on the rising and the other on the descending arm of the temperature curve, was that in those like α Herculis we have enormous variability as well as bright lines and flutings indicative of sparse swarms, while in those like the Sun the production of such phenomena is almost unthinkable. The special variability of stars of my Group II. (Secchi's type III.) and the production of bright lines at maximum is now freely acknowledged. On this point Prof. Pickering remarks [1]:—

"Long period variables in general are of the third type, and have the hydrogen lines bright when near their maxima, as stated above. This property has led to the discovery of more

[1] *Astronomy and Astro-Physics*, 1893, p. 721.

than twenty objects of this class, and no exception has been found of a star having this spectrum whose light does not really vary. Of the variables of long period which have been discovered visually, the hydrogen lines have been photographed as bright in forty-one, the greater portion of the others being too fainter too red to be studied with our present means."

As said before, it seems impossible to imagine how our Sun, as it proceeds along its "order of growth," should change into a body with such characteristics as these. But on this point we must wait for more large scale photographic spectra; in other words, more facts.

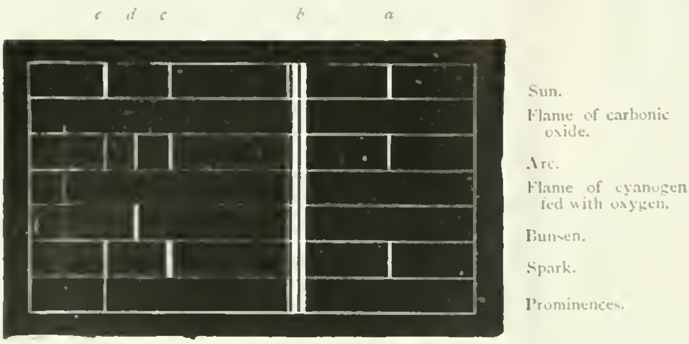

FIG. 39.—Showing the various intensities of the lines of magnesium as seen under different conditions.

Associated with this change in the order of evolution, Prof. Pickering classes the chief stars in Orion, such as Bellatrix, characterised by spectra containing hydrogen and a few other dark lines of unknown origin, as early forms. On this point I may also quote the following from Prof. Campbell (*Astronomy and Astro-Physics*, 1894, p. 475):—

"In conclusion, I think we can say, from the foregoing observations, that the spectra of the Wolf-Rayet stars are not closely related to any other known type. They appear to have several points in common with the nebular and Orion type spectra; but the last two appear to be much more closely related to each other than to the Wolf-Rayet spectra. It is therefore difficult to place these stars between the nebulæ and Orion stars. They certainly do not come *after* the Orion stars, and one does not like to place them before the nebulæ. We can probably say that the bright lines are chromospheric, owing their origin to very extensive and highly-heated atmospheres, but showing very little relation, in constitution and physical condition, to that of our own Sun. For the present, at least, this type of spectrum must be considered as distinct from every other known type, just as the nebular spectrum is distinct, and like the nebular spectrum containing lines whose origin cannot now be assigned."

Although Dr. Vogel and others apparently still hold in the main to the classification which assumes that all stars were created hot, and that nebulæ have nothing to do with them; that, in short, every star began in the highest stage of temperature, so that the whole history of every star in the heavens has been a process of cooling, there are signs of wavering here and there. Some of the definitions are being "edited" and re-edited to fit the facts which the photographic record is pouring in upon us. I may take, as an instance, the following statement made by Dr. Scheiner with reference to α Cygni, which is classified by Dr. Vogel as a solar star.

"These figures plainly show that the spectrum of α Cygni, in spite of the large number of its lines, has no resemblance with that of the sun. While it is possible to identify most of the lines with solar lines in respect to their position, yet the total lack of agreement as to intensity of the lines makes many of these identifications worthless."

The "figures" referred to are micrometer measures of a photograph. My experience in these matters is that it is a pure waste of time to measure a photograph until it has been compared with others to which it is important to refer it, enlarged up to the same scale. In this I think I carry Prof. Keeler with me (*Astronomy and Astro-Physics*, 1894, p. 485). "The coincidence of . . . lines is shown more beautifully by inspection of . . . photographs than by any process of measurement." Thus a comparison of the spectra of α Cygni and of the Sun *which Dr. Vogel classes together*, shows at once the dissimilarity pointed out above without any measurement whatever. I am glad, however, to find that Dr. Scheiner now regards the identification as "worthless," because it is such differences as these which have compelled me to reject Dr. Vogel's classification.

Dr. Scheiner then goes on:—

"The magnesium line at λ 4481 is the strongest in the entire spectrum. The other strong lines coincide for the most part with the fainter solar lines. The presence of numerous iron lines can be scarcely doubted, but here again we have the peculiar phenomenon that the fainter, instead of the stronger, lines occur. We may conclude from all these facts that very different conditions as to temperature must prevail in α Cygni from those in the stars of class Ia." (Scheiner's "Astronomical Spectroscopy," Frost's translation, p. 247.)

Much of the work of the future, which eventually must smooth down all differences between stellar classifications, must consist of the study of single lines in the spectra of different stars, and I am rejoiced to find that the Potsdam observers are at length beginning to take this matter up. Dr. Scheiner, one of the Potsdam assistants, has, as seen above, called attention to the behaviour of the line 4481 of magnesium, and agrees that the variations in the line observed are due to differences of temperature, and that therefore it may be used as a stellar thermometer.[1]

But for this work an acquaintance with the literature of the subject is desirable. Had Dr. Scheiner been acquainted with it, I am certain he would have done me the honour to quote, or at all events to refer to, a communication I made to the Royal Society (16 years ago!), pointing out that the line in question was visible only at high temperatures, and that such work would help us in the study of "the atmospheres of the hottest stars."[2] In the same connection, in the "Chemistry of the Sun," published in 1887, I gave the diagrams, here reproduced, indicating the lines, visible at various temperatures in the laboratory, and in the Sun and prominences.

Having said so much on the different classifications of stars, and indicated, I trust judicially, that the one suggested by the meteoritic hypothesis is so far holding its own, I now pass on to some recent work which was undertaken to test it by a limited photographic survey. In the first instance I had used the eye observations of others; a study of spectra, entirely photographic, it was hoped would enable an independent estimate to be formed as to the validity of the hypothesis.

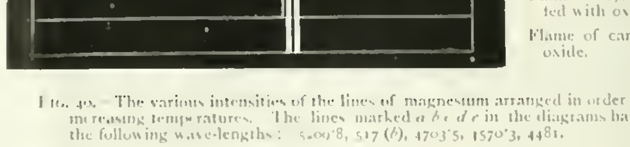

FIG. 40.—The various intensities of the lines of magnesium arranged in order of increasing temperatures. The lines marked *a b c d e* in the diagrams have the following wave-lengths: 5209·8, 517 (*b*), 4703·5, 4570·3, 4481.

The conclusions I came to in the first instance were necessarily based on observations made by others, for the reason that my own work up to that time had been chiefly directed to the Sun.

So soon, however, as my solar work rendered it necessary to determine the Sun's true place among the stars in regard to its

[1] "Astronomical Spectroscopy," p. viii.

[2] *Roy. Soc. Proc.* vol. xxx. p. 22, 1879.

temperature and physical conditions, arrangements were made to photograph the spectra of stars and nebulæ, in order to test the view, employing a quite new basis of facts; this new basis of the inquiry consists of 443 photographs of 171 of the brighter stars.

Having this new and accurate basis of induction, the objects were to determine whether the hypothesis founded on eye observations is also demanded by the photographs, and in the affirmative case to discover and apply new tests of its validity, or otherwise.

The results as yet obtained are not sufficient to permit a discussion of all points bearing upon the new classification, but most of the crucial ones are certainly covered by the photographs already obtained.

The main instrument employed in the work has been a 6-inch refracting telescope, with an object-glass made and corrected for G by the Brothers Henry. This was at first used in conjunction with a prism of $7\frac{1}{2}°$ of dense glass by Hilger. The object-glass and prism are fixed at the end of a wooden tube, which is attached to the side of the 10-inch equatorial, at such an angle that the spectrum of a star falls on the middle of the photographic plate when its image is at the centre of the field of the larger instrument. The camera is arranged to take plates of the ordinary commercial size, $4\frac{1}{4} \times 3\frac{1}{4}$ inches. The spectra obtained with this instrument are 0·6 inch long from F to K. An excellent photograph of the spectrum of a first magnitude star can be obtained with an exposure of five minutes. Afterwards a 6-inch prism, with a refracting angle of 45°, obtained from the Brothers Henry, was used with the Henry 6-inch object glass. The spectra obtained with the latter are two inches long from F to K, and the definition is exquisite. In some photographs the calcium line at H is very clearly separated from the line of hydrogen, which occupies very nearly the same position. It is unnecessary to swing the back of the camera in order to get a perfect focus from F to K. The deviation of the prism is so great that it would be very inconvenient to incline the tube which supports it at the proper angle to the larger telescope. When photographing the spectrum of a star, therefore, the star is first brought to the centre of the field of the large telescope, and the proper deviation is then given by reading off on the declination circle. This method has been found to work quite satisfactorily.

FIG. 41.—Objective prism fitted to object-glass.

With this combination the exposure required for a first magnitude star is about twenty minutes. The method of mounting the prism is shown in Fig. 41.

For the fainter stars, the 6-inch prism of $7\frac{1}{2}°$ has been adapted to a Dallmeyer rectilinear lens of 6 inches aperture and 48 inches focal length. At times prisms of $7\frac{1}{2}°$ have been used on a 10-inch equatorial.

Since the spectrum of a point of light such as a star is a line so fine that the spectral lines would not be measurable, it is necessary to give it breadth. This is done by adjusting the prism so that the spectrum lies along a meridian of R.A. and altering the rate of the clock.

J. NORMAN LOCKYER.

(*To be continued.*)

THE IRON AND STEEL INSTITUTE.

THE annual summer meeting of the Iron and Steel Institute was held in Birmingham last week, commencing Tuesday, the 20th inst., and extending over Friday, the 23rd inst. Sir David Dale, the President, took the chair at the sittings for the reading of papers, and it may be said here that the meeting was remarkably successful throughout, being one of the pleasantest and most instructive gatherings that has been held for a long time past; both Mr. Brough, the Secretary of the Institute, and the local committee are to be congratulated on the excellence of their arrangements.

There were twelve papers down for reading and discussion, of which the following is a list:—

"On the Direct Puddling of Iron," by E. Bonehill (Marchienne-au-Pont, Belgium).

"On the Production of Iron by a New Process," by R. A. Hadfield, member of Council (Sheffield).

"On the Thermo-Chemistry of the Bessemer Process," by Prof. W. N. Hartley, F.R.S. (Dublin).

"On the Hardening of Steel," by H. M. Howe (Boston, U.S.A.).

"On the Mineral Resources of South Staffordshire," by H. W. Hughes (Dudley).

"On the Iron Industry of South Staffordshire," by D. Jones, Secretary of the South Staffordshire Ironmasters' Association (Shifnal).

"On the Iron Industry of the South of Russia," by George Kamensky (St. Petersburg).

"On Cooling Curves and Tests of Cast Iron," by W. J. Keep (Detroit, U.S.A.).

"On the Analysis of Ferro-Chromium," by E. H. Saniter (Wigan).

"On Small Cast Ingots," by R. Smith-Casson (Birmingham).

"On Tests of Cast Iron," by T. D. West (Sharpsville, Pennsylvania).

"On Nickel Steel," by H. A. Wiggin (Birmingham).

The papers of Mr. West and Mr. Keep were taken as read, all the others being read and discussed.

On the members assembling on Tuesday morning, in the Council House of Birmingham Corporation, they were welcomed by the Mayor, and by the members of the local reception committee.

The first paper taken was that by Mr. D. Jones, on the iron industry of South Staffordshire. This was an interesting contribution, but mainly historical in its character. It dealt with the rise and progress of the iron industry of the district from its earliest days, and, in treating of more modern times, pointed out how the production of wrought-iron had decreased as steel had taken its place, although a good deal of puddled iron is still produced in the district. The paper of Mr. Hughes, on the mineral resources of South Staffordshire, was very much of the same character, and gave, in a convenient form, many facts relating to the subject.

M. Bonehill's paper on the direct puddling of iron was next read. This process appears to be a revival of, and doubtless an improvement on, a method of puddling which was proposed, and to a limited extent carried out, in the earlier years of the century, but which never obtained any great hold in the iron

industry. It consists, briefly, in running molten iron from the blast furnace into a reservoir, and from thence letting it flow into the puddling furnace, the latter being of larger description than is generally used. It is obvious that with this process, as compared to the ordinary method of feeding the puddling furnace with cold pig, there is a saving of fuel, inasmuch as the metal does not require melting: on the other hand, the difficulty of getting a uniform product, owing to the inability to mix various kinds of pig, has to be overcome. Apparently the author has been successful in the latter respect, although how he has accomplished his end was not stated in the paper; the tests given, however, indicate that a superior quality of iron is produced.

Mr. Kamensky's paper on the iron industries of South Russia was, like the two first contributions, of an historical nature. In this case, however, there was less of ancient history in the memoir, and necessarily so, as the production of iron in Russia, as an industry of importance, is of essentially modern growth. It is true that iron-making has been carried on in Russia for a long time past, but it is only within the last year or two that any great strides have been made. Now, however, there are several works in operation, and it appears likely that more will follow: so Russia may in her turn put in a claim for a share of the opening markets of the world. This is a fact that British steelmakers may perhaps look on not altogether with satisfaction; but it is inevitable. Only by increased exertion can British manufacturers maintain their position in the markets of the world; but there is one point, however, worthy of attention. If Russia is about to start many steel works, large quantities of plant and machinery will be required. It is proposed that the Institute shall next year hold its summer meeting in Russia. The suggestion is a bold one, but is worthy of consideration, for it is only by pushing abroad that steel makers can hope to keep abreast of the times. The days are past when the manufacture of iron and steel was almost entirely centred in England. Now there are works all over the world, under intelligent and scientific management. It is unreasonable to expect that we, in England, will continue to originate all new and valuable processes, and it is well, therefore, that English manufacturers should go abroad to reap the advantages of foreign research and practice; just as foreign manufacturers have in times past, and are still, reaping the advantage of English experience and study.

The reading and discussion of the above four papers constituted the business of the first sitting. The afternoon of that day—Tuesday, the 20th inst.—was devoted to visits to works. One party proceeded to the Staffordshire Steel and Ingot Iron Company's establishment at Bilston, where the operations of rolling sections and plates were witnessed. A large quantity of basic steel is produced at these works; and the method of dealing with the basic slag, which is largely used for agricultural purposes, was inspected with interest by the members. Another party visited the Electric Construction Company's works at Wolverhampton; whilst, again, others distributed themselves amongst various works in Birmingham.

On assembling again on Wednesday morning the first paper taken was that contributed by Prof. Hartley, on the thermochemistry of the Bessemer process. This was an exceedingly interesting paper, which those engaged in subjects of this nature would do well to read in full in the *Transactions* of the Institute. The author commenced by saying that the flame issuing from the mouth of a Bessemer converter was first investigated by Sir Henry Roscoe in 1863 (see Manchester Literary and Philosophical Society's *Proceedings*, vol. iii. p. 57, and *Philosophical Magazine*, vol. xxxiv. p. 437); by Leilegg (see *Sitzungsberichte Kaiserl. Akademie der Wissenschaften*, Wien, vol. lvi. part ii.); and by Marshall Watts in 1867 (see *Philosophical Magazine*, vol. xxxiv. p. 437); by Tunner (see Dingler's *Polytechnisches Journal*, vol. clxxviii. p. 465); by J. M. Silliman (see *Philosophical Magazine*, vol. xli. p. 1); by von Lichtenfels (see Dingler's *Polytechnisches Journal*, vol. cxci. p. 213); by Spear Parker (*Chemical News*, vol. xxii. p. 25); by Kupelwieser (*Oesterreichische Zeitschrift für Berg- und Hüttenwesen*, No. 8, p. 59, 1868); by Brunner and Wedding in 1868 (see *Zeitschrift für das Berg-Hütten-und Salinenwesen im preussischen Staate*, vol. xvii. p. 117, 1869); and also by A. Greiner in 1874 (see *Revue Universelle des Mines*, vol. xxxv. p. 625). Up to the present time the nature of the spectrum, the cause of its production, and sudden disappearance when decarburisation of the metal takes place, and the connection between the decarburisation of the metal and the extinction of the spectrum, have not been satisfactorily explained. According to Roscoe, Leilegg, Kupelwieser, and Spear Parker, the spectrum is characterised by bands of carbon or of carbon monoxide, which disappear when all the carbon is burnt out of the metal. On the other hand, Simmler, Brunner, von Lichtenfels, and Wedding hold that the spectrum is not due to carbon, or to carbon monoxide, but to manganese and other elements in pig iron. Dr. Marshall Watts had come to the conclusion that it was not the spectrum of carbon in any form, nor of manganese, but that of manganetic oxide. Leilegg proved that carbon monoxide yields a continuous spectrum, which causes the bright spectrum of the Bessemer flame; but he also attributed certain lines, or bands, to the high temperature of the carbon monoxide. Marshall Watts established the fact that six lines of the spectrum of iron were present in the Bessemer spectrum; Greiner observed in flame from highly manganiferous pig iron the spectrum of manganese. The author concluded this part of his paper by pointing out the fact that notwithstanding the great advance which has been made in spectroscopy during the last twenty years, our knowledge of flame spectra has remained almost stationary, although much attention has been directed to the spectra of the elements as we obtain them at higher temperatures by vapourising substances in the electric arc, and by the transmission of electric sparks.

Prof. Hartley next proceeded to describe a method of accurately investigating the Bessemer flame. He pointed out that the determination of wave-length of lines and bands by eye observation only, with instruments of the usual form, is laborious under the most advantageous conditions, but it is especially so when the spectra are constantly changing; and it becomes practically impossible when the lines and bands to be measured are in the ultra-violet. Spectra which are recorded by photography are capable of being more accurately measured at leisure by very simple means; moreover, they constitute a permanent record; and for accurate observations, determinations of wave-lengths are absolutely essential. The author next went on to describe a modification of the instrument he had originally designed for this purpose. This is described in the *Proceedings* of the Royal Dublin Society, and also in Thorpe's "Dictionary of Applied Chemistry," article "Spectroscope." This instrument was especially designed for use in steel work, particularly for studying the spectra of flames and heated gases of open-hearth furnaces. It was therefore desirable that it should give a fair amount of dispersion at the less refrangible end of the spectrum. A train of four quartz prisms was at first arranged, and a camera was fitted with a rack and pinion movement to the frame holding the dark slide, so that as many as thirty spectra could be photographed on one plate. The stand, however, was found to be too light. Instead of four quartz prisms, a single prism of calcite may be employed if the surfaces are well protected from dust; the prism table was fixed so that it could be placed in almost any required position. The camera was of metal with an eye-piece behind the frame for the dark slide, so as to make it available for visual observation. In a circular box at the end of the camera, which was reduced in size, the dark slide can be fixed at any angle, as it is rotated by means of a toothed wheel. The prisms move automatically with the camera, and in order to secure the minimum angle of deviation to the mean rays photographed there is a condensing lens of 3-inch focus. There is a slit plate, covered with thin quartz to exclude dust and dirt, and upon this the image of the flame was projected. A metal plate, with a V-shaped piece cut out at one end, slides over the slit plate, and serves to shorten or lengthen the slit and secure a greater or smaller number of spectra on one photographic plate. In some cases a photograph was taken every half-minute, from the commencement to the termination of the "blow." This could be accomplished only by the use of the arrangement described, as the plates were no more than 3 inches by $2\frac{1}{2}$ inches. The instrument was focussed by a photograph of sun spectra.

The author also described an ingenious arrangement consisting of yellow cloth, with armholes and sleeves fitted with elastic, by means of which he carried on development of the photographs without use of a dark room. By this apparatus it was shown that a large number of lines in the spectrum of the Bessemer flame were coincident with lines in the solar spectrum, and the position of the lines and edges of bands with respect to the sodium line was recorded, being measured with a micrometer screw and microscope. Enlargements were made in which the spectra were magnified ten diameters. Several interpolation curves were drawn by which linear measurements were

reduced to oscillation-frequencies, and by means of Barlow's mathematical tables these were reduced to wave-lengths which are the reciprocals of the oscillation-frequencies. The author then went on to describe some of the difficulties met with in obtaining measurements of bands, due to alterations in width, or to their becoming less distinct at the edges. The question is dealt with in "Flame Spectra of High Temperatures," *Philosophical Transactions*, 1894, part 1.

Prof. Hartley had carried out experiments at Crewe, and at Dowlais, in South Wales. Results obtained by photography of the spectrum of the Bessemer flame were given in the paper. For the details we must refer our readers to the original memoir. As the author pointed out, the Bessemer spectrum is a complex one, which exhibits differences in constitution during different periods of the blow, and even during different intervals of the same period. Watts had observed that the spectrum differs in different works, owing to variations of temperature and the composition of the metal blown. After discussing the various opinions held by previous investigators as to the utility of spectrum analysis in steel making—on which subject inquirers are by no means agreed the cause of the non-appearance of lines at the termination of the blow is discussed. Prof. Hartley then proceeded to what was perhaps the most interesting part of his paper, namely, the temperature of the Bessemer metal and of the flame, and the use of the spectrum as an index of temperature. Watts concluded that though the temperature of the flame was above the melting point of gold, it was below that of platinum. Le Chatelier (*Comptes rendus*, vol. cxiv. p. 670) was of opinion that the temperature of the Bessemer converter during the boil is 1330° C., at the finish 1580° C., while the steel in the ladle is at 1640° C. There is no measure of the temperature at the hottest period of the boil, and unless the metal in the converter is cooled during the last minute of the blow, which some of the author's photographs indicated, it was difficult to understand how its temperature could be raised by the addition of the cooler spiegeleisen and ferro-manganese. The rise of temperature at this period could be accounted for by the after-blow. Of course when the metal is charged with oxygen, the additional spiegeleisen, containing carbon and manganese, would cause the combustion of these elements. When the oxyhydrogen flame spectra of the manganese, magnetic oxide of iron, and ferric oxide are photographed, the number of lines and bands in the spectra are not more numerous than with a Bessemer flame spectrum of only half a minute's exposure, although the above spectra may have received any exposure from thirty to eighty minutes. When a substance emits a spectrum composed of bands and lines, it is evidence of the presence of the substance in the flame in a state of glowing vapour; when the same substance emits two spectra, one differing from the other by the largely increased number of bands or lines, it is evidence that either the substance is more copiously vapourised, or that the temperature of the vapour is higher. When a simple spectrum changes to one of a more complex character, the alteration is due to an increase in temperature, other things being equal. Similarly when a spectrum extends through the visible rays into the ultra-violet region, and an increase is observed in the number and intensity of the ultra-violet rays, nothing but an increase of temperature will serve to account for the change in the spectrum. No increase of material in the flame would increase the refrangibility of the rays emitted by its vapour; hence the study of the ultra-violet spectra of flames by the photographic method becomes an important line of investigation.

After pointing out the difficulty of ascertaining the maximum temperature of any flame (as such temperature may exist over but a very small area), and giving an instance, the author states that Le Chatelier's recent measurements of the temperature of furnaces have given numbers considerably lower than those usually accepted. Langley's estimate of the temperature of the Bessemer flame at 2000° C. because platinum appears to be rapidly melted in it—is not to be relied upon. Le Chatelier finds that the metal is not fused but dissolved in drops of molten steel. Marshall Watts observed that the sodium lines 5681 and 5687 may be employed as an index of temperature, since they are present in the spectrum of any flame containing sodium the temperature of which is hot enough to melt platinum, but they do not appear at lower temperatures. The Bessemer flame does not show this double line, but only the D lines, neither does it show lithium orange lines, which appear at a somewhat lower temperature. It may therefore be concluded that the flame is not hot enough to produce these lines. The proportion of sodium in the Bessemer flame is evidently very small from the narrowness and want of intensity of the D lines, and the fact that they are not seen reversed in any spectrum; hence, though the temperature may be high enough, the quantity of material present is not sufficiently large to yield the lines 5681 and 5687.

We have not space to follow the author in all the interesting details of his reasoning, but we have perhaps said enough to indicate his line of thought. He later points out that, judging by the number of lines and bands belonging to iron and manganese, which have been photographed in the spectrum of the Bessemer flame, the temperature must in any case nearly approach that of the oxyhydrogen flame, even if it does not very generally exceed it. The paper concluded with particulars of the heat of combustion of the oxidisable impurities in pig iron. He calculates, as far as data are available, the absolute heating effect of such oxidation. The temperature retained according to these calculations amounts to 1454° C. above that of molten cast iron. This, however, is a theoretical value, and allowance must be made for the specific heats of the gases, the metal, and the slag, which are greater at the elevated temperatures than at the temperatures at which the numbers representing specific heats were determined. The specific heat of the converter must be considerable, but it must be remembered that it is already heated to the temperature of the molten metal; but even if we allow that 50 per cent. of the heat is absorbed, or conveyed away, we should then have the temperature 727° C. above that of the molten pig iron; and thus, with grey iron, at 1220° C. the metal may have acquired a temperature of more than 1947° C., which is very considerably above the melting point of platinum.

The discussion which followed the reading of this paper was interesting, but no new points of importance were added. Mr. Bauerman considered that the author was right in laying stress on the temperature of the flame as well as on the materials in the converter. Mr. J. Stead pointed out that some of the calculations were made in cases where the composition of the metal was very different to that common in England. Mr. Tucker also pointed out the difficulty in arriving at any conclusion owing to the variation in metal used, and he referred to the effect of a temperature of dissociation which might be obtained if the metal were sufficiently rich in silicon. His own experiments supported those of Prof. Hartley, that the temperature was certainly at times considerably above the melting point of platinum, and he was inclined to think that the temperature of dissociation was often reached.

The next paper was also one of considerable scientific interest. It was Mr. Howe's contribution on the hardening of steel, and was read in abstract by Mr. Brough, the Secretary of the Institute. As the paper had been received so recently, copies of it had not been distributed, and it was manifestly impossible to discuss a memoir of this abstruse nature at first sight, especially as the paper was not read in full. It was therefore wisely determined to have the text corrected, after which the paper will be distributed, and its discussion taken at the next meeting in May. For the present, it will suffice to say that the author deals largely with the vexed problem of the allotropic state of iron. It would have been a pity to have discussed the paper on the spot, as neither Prof. Roberts-Austen nor Prof. Arnold were present; neither had M. Osmond been able to send his usual written contribution. In fact, the only person present whose name has become at all prominently identified with the states of iron treated was Mr. Hadfield, who spoke briefly, saying that he had not had time to master the paper. We will, therefore, defer our abstract of this memoir until the time comes to give an account of the next meeting.

Mr. R. A. Hadfield's paper on the production of iron by a new process was next read. The author's object has been to obtain a pure iron; for which purpose he had had recourse to aluminium as an agent. The first result was that he made an alloy of iron and aluminium very rich in the latter constituent, there being no less than 36 per cent. present. In spite of being a failure, so far as the object in view was concerned, a very interesting result was obtained; for although there was no more than a trace of carbon present, the alloy was hard enough to scratch glass. Proceeding on the same lines, however, and working with ferrous oxide and granulated aluminium, a sample of iron containing 99·75 per cent. of that metal was finally obtained at the very moderate cost of about eighteen pence per pound.

Mr. Saniter's paper, describing a new method for the analysis of chrome and ferro-chromium, was the last read at this sitting. This is a further extension of Mr. Stead's modification of Dr. Clarke's process, and has the great advantage of reducing the time occupied in the analysis.

On the afternoon of this day there were several excursions, the chief of which was to Worcester, where the works of the Royal Porcelain Company were inspected. Another party visited the Round Oak Iron and Steel Works, while others proceeded to the glass works, fireclay works, small arms factories, and to other works in and around Birmingham. In the evening there was a very successful reception and entertainment in the Edgbaston Botanical Gardens.

The final sitting of the meeting was on Thursday of last week, when a paper by Mr. Henry Wiggin, on nickel steel, was first taken. In this contribution the advantages of nickel steel as a constructive material were brought forward; its great tensile strength combined with excessive ductility being dwelt upon. Another advantage possessed is freedom from corrosion, as compared with ordinary steel. Instances were given of the nickel steel containing 3½ per cent. of nickel, which had a tensile strength fully 30 per cent. higher than ordinary steel, and an elastic limit at least 75 per cent. higher. The author does not give any details in regard to cost, which is naturally higher than that of ordinary steel; but speaking upon the subject generally, he was of opinion that the additional price that would have to be charged would generally be more than compensated for by increased efficiency. In the discussion, Mr. W. Beardmore, of Glasgow, said he had been making large quantities of nickel steel for the last two years. This was for armour-plates, but he was now preparing a series of tests to submit to Lloyd's with a view to introducing the material for marine purposes. Mr. Jeremiah Head, who had lately visited America, said that at the works of Mr. Carnegie he had seen large quantities of nickel steel produced at a cost, he was told, of about £7 a ton; but there natural gas of great richness was available. Mr. Thompson, of New York, who had been largely engaged in the manufacture of nickel steel, said that in America 50,000 to 75,000 tons of this material had been produced during the last three years. A German chemist had found that with an alloy of 15 per cent. of nickel almost a new metal was made having a tensile strength of 244,000 lbs. to the square inch, and an elastic limit as high in proportion. He estimated that to build a large battleship of nickel steel would add but 2 per cent. to her cost, whilst the efficiency would be doubled. Mr. Thomas Turner afterwards pointed out that nickel steel was supposed to have a wide range of extension and contraction with variations of temperature, so that if a ship went to the polar regions it might become even feet shorter in its length.

Mr. Smith-Casson's paper, on small cast ingots, was next read. The author claims to have got very good results by casting ingots together from the bottom. This was the last paper read at the meeting.

Thursday afternoon was devoted to an excursion to Stratford-on-Avon, whilst on the following day, Friday, an excursion was made to Kenilworth and to Warwick, where members and their friends were entertained at the Castle by Lord and Lady Warwick.

THE SPECTRUM OF HELIUM.[1]

IN the *Chemical News* for March 29 last (vol. lxxi. p. 151), I published the results of measurements of the wave-lengths of the more prominent lines seen in the spectrum of the gas from clèveite, now identified with helium. The gas had been given to me by the discoverer, Prof. Ramsay; and being from the first batch prepared, it contained other gases as impurities, such as nitrogen and aqueous vapour, both of which gave spectra interfering with the purity of the true helium spectrum. I have since, thanks to the kindness of Profs. Ramsay and J. Norman Lockyer, had an opportunity of examining samples of helium from different minerals and of considerable purity as far as known contamination is concerned. These samples of gas were sealed in tubes of various kinds and exhausted to the most luminous point for spectrum observations. In most cases no internal electrodes were used, but the rarefied gas was illuminated solely by induction, metallic terminals being attached to the outside of the tube.[1] For photographic purposes a quartz window was attached to the end of the tube, so that the spectrum of the gas could be taken "end on."

[1] From the *Chemical News*, August 2[illegible].

My examinations have chiefly been made on five samples of gas.

(1) A sample from Prof. Ramsay in March last. Prepared from clèveite.

(2) A sample from Prof. Ramsay in May last. Prepared from a specimen of uraninite sent to him by Prof. Hillebrand. Gas obtained by means of sulphuric acid; purified by sparking.

(3) A sample from Prof. Ramsay in June last. Prepared from bröggerite.

(4) A sample from Prof. Lockyer in July last. Prepared by a process of fractional distillation from a sample of bröggerite sent by Prof. Brögger.

(5) A sample of gas from Prof. Ramsay, "Helium Purissimum." This was obtained from mixed sources, and had been purified to the highest possible point.

In the following table the first four samples of gas will be called:—(1) "Clèveite, R."; (2) "Uraninite, R"; (3) "Bröggerite, R"; and (4) "Bröggerite, L." Only the strongest of the lines, and those about which I have no doubt, are given. The wave-lengths are on Rowland's scale.

The photographs were taken on plates bent to the proper curvature for bringing the whole spectrum in accurate focus at the same time. The spectrum given by a spark between an alloy of equal atoms of mercury, cadmium, zinc, and tin, was photographed at the same time on the plate, partially overlapping the helium spectrum; suitable lines of these metals were used as standards. The measurements were taken by means of a special micrometer reading approximately to the 1/100,000th inch, and with accuracy to the 1/10,000th of an inch. The calculations were performed according to Sir George Stokes's formula, supplemented by an additional formula kindly supplied by Sir George Stokes, giving a correction to be applied to the approximate wave-lengths given by the first formula, and greatly increasing the accuracy of the results.

Wave-length.	Intensity.	
7065·5	5	A red line, seen in all the samples of gas. Young gives a chromospheric line at 7065·5.
6678·1	8	A red line, seen in all the samples of gas. Thalén gives a line at 6677, and Lockyer at 6678. Young gives a chromospheric line at 6678·3.
5876·0	30	The characteristic yellow line of helium, seen in all the samples of gas. Thalén makes it 5875·9, and Rowland 5875·98. Young gives a chromospheric line at 5876.
5062·15	3	
5047·1	5	A yellow-green line, only seen in "Helium Puriss." and in "Bröggerite, R," and "L." Thalén gives the wave-length as 5048.
5015·9	7	A green line seen in all the samples of gas. Thalén gives the wave-length 5016. Young gives a chromospheric line at 5015·9.
4931·9	3	
4922·6	10	A green line, seen in all the samples of gas. Thalén gives the wave-length 4922. Young gives a chromospheric line at 4922·3.
4870·6	7	A green line, only seen in "Uraninite, R." Young gives a chromospheric line at 4870·4.
4847·3	7	A green line, only seen in "Uraninite, R." Young gives a chromospheric line at 4848·7.
4805·6	9	A green line, only seen in "Uraninite, R." Young gives a chromospheric line at 4805·25.
4764·4	2	There is a hydrogen line at 4764·0.
4735·1	10	A very strong greenish blue line, only seen in "Uraninite, R."
4713·4	9	A blue line, seen in all the samples of gas. Thalén's measurement is 4713·5. Young gives a chromospheric line at 4713·4.
4658·5	8	A blue line, only seen in "Uraninite, R."
4579·1	3	A faint blue line, seen in "Uraninite, R." Lockyer gives a line at 4580, from certain minerals. I can see no traces of it in the gas from Bröggerite. A hydrogen line occurs at 4580·1.

[1] *Journal of the Institution of Electrical Engineers*, part 91, vol. xx., Inaugural Address by the President, William Crookes, F.R.S., Jan. 15, 1891.

Wave-length.	Intensity.	
4559·4	2	Young gives a chromospheric line at 4558·9.
4544·1	5	
4520·9	3	A faint blue line, seen in "Uraninite, R." Lockyer gives a line at 4522, seen in the gas from some minerals. Young gives a chromospheric line at 4522·9. It is absent in the gas from Bröggerite.
4511·4	5	A blue line, seen in "Uraninite, R," but not in the others. It is coincident with the strong head of a carbon band in the CO_2 and Cy spectrum.
4497·8	2	There is a hydrogen line at 4498·75.
4471·5	10	A very strong blue line, having a fainter line on each side, forming a close triplet. It is a prominent line in all the samples of gas examined. Young gives the wave-length 4471·8 for a line in the chromosphere, and Lockyer gives 4471 for a line in gas from Bröggerite.
4435·7	9	Seen in "Helium Puriss."
4437·1	1	Young gives a chromospheric line at 4437·2.
4428·1	10	These two lines form a close pair. I can only see them in "Uraninite, R." No trace of them can be seen in the gases from other sources. Young gives chromospheric lines at 4426·6 and 4425·6.
4424·0	10	
4399·0	10	A strong line, only seen in "Uraninite, R." Absent in the gas from the other sources. Lockyer gives a line at 4398 in gas from certain minerals. Young gives a chromospheric line at 4398·9.
4386·3	6	Seen in all the samples of gas. Young gives a chromospheric line at 4385·4.
4378·8	8	These two lines form a pair seen in "Uraninite, R," but entirely absent in the others.
4371.0	8	
4348·4	10	Seen in "Uraninite, R." Lockyer finds a line at 4347 in the gas from certain minerals.
4333·9	10	Probably a very close double line. Seen in "Uraninite, R," and "Clèveite, R." Not seen in the other samples. Lockyer gives a line in the gas from certain minerals at 4338.
4298·7	6	Only seen in "Uraninite, R." Young gives a chromospheric line at 4298·5.
4281·3	5	Only seen in "Uraninite, R."
4271·0	5	Only seen in "Uraninite, R." The strong head of a nitrogen band occurs close to this line.
4258·8	7	Seen in all the samples of gas.
4227·1	5	Only seen in "Uraninite, R." Young gives a chromospheric line at 4226·89
4198·6	9	These three lines form a prominent group in "Uraninite, R," they are very faint in "Clèveite, R," and in Bröggerite, L," but are not seen in "Bröggerite, R."
4189·9	9	
4181·5	9	
4178·1	1	An extremely faint line. Lockyer gives a line at 4177, seen in the gas from certain minerals, and Young gives a chromospheric line at 4179·5.
4169·4	6	Seen in "Helium Puriss."
4157·6	8	A strong line in "Uraninite, R," very faint in "Bröggerite, R," and "L," not seen in "Clèveite, R."
4143·9	7	Strong in "Clèveite, R," in "Helium Puriss.," and in "Bröggerite, L." It is faint in "Uraninite, R," and not seen in "Bröggerite, R." Lockyer gives a line at 4145 in gas from certain minerals.
4121·3	7	Present in all the gases except "Clèveite, R."
4044·3	9	Present in "Uraninite, R," and "Clèveite, R." Absent in the others.
4026·1	10	These lines form a very close pair, seen in all the samples of gas, except "Bröggerite, R." Lockyer finds a line in Bröggerite gas at 4026·5.
4024·15	6	
4012·9	7	Seen in all the samples of gas.
4009·2	7	Seen in "Helium Puriss."
3964·8	10	The centre line of a dense triplet. Only seen in "Clèveite, R," in Helium Puriss.," and "Bröggerite, L." Hale gives a chromospheric line at 3964.
3962·3	4	Seen in all the samples of gas.
3948·2	10	Very strong in "Uraninite, R," very faint in "Clèveite, R," and not seen in the others. Lockyer finds a line in gas from Bröggerite at 3947. There is an eclipse line at the same wave-length.
3925·8	2	Seen in "Helium Puriss."
3917·0	2	Seen in "Helium Puriss."
3913·2	4	Only seen in "Uraninite, R," and "Helium Puriss." Hale gives a chromospheric line at 3913·5.
3890·5	9	A very strong triplet, seen in all the samples of gas. Lockyer finds a line having a wave-length 3889 in gas from Bröggerite. Hale gives a chromospheric line at 3888·73. There is a strong hydrogen line at 3889·15
3888·5	10	
3885·9	9	
3874·6	6	Only seen in "Uraninite, R."
3867·7	8	Seen in "Helium Puriss."
3819·4	10	Seen in all the samples of gas. Deslandres gives a chromospheric line at 3819·8.
3800·6	4	Seen in "Helium Puriss."
3732·5	5	Seen in "Helium Puriss." Hale gives a chromospheric line at 3733·3
3705·4	6	Seen in all the samples of gas. Deslandres gives a chromospheric line at 3705·9.
3642·0	8	Only seen in "Uraninite, R."
3633·3	8	Seen in "Helium Puriss."
3627·8	5	Only seen in "Uraninite, R."
3613·7	9	Seen in "Helium Puriss."
3587·0	5	Seen in "Helium Puriss."
3447·8	8	Seen in "Helium Puriss."
3353·8	5	Seen in "Helium Puriss."
3247·5	2	Seen in "Helium Puriss."
3187·3	10	The centre line of a close triplet. Very faint in "Clèveite, R," and "Uraninite, R." and strong in "Helium Puriss." and in "Bröggerite, L." It is not seen in "Bröggerite, R."
2944·9	8	A prominent line, only seen in "Helium Puriss." and in "Bröggerite, L."
2536·5	8	Seen in "Helium Puriss." A mercury line occurs at 2536·72.
2479·1	4	Seen in "Helium Puriss."
2446·4	2	Seen in "Helium Puriss."
2419·8	2	Seen in "Helium Puriss."

Some of the more refrangible lines may possibly be due to the presence of a carbon compound with the helium. To photograph them, a long exposure, extending over several hours, is necessary. The quartz window has to be cemented to the glass with an organic cement, and the long-continued action of the powerful induction current on the organic matter decomposes it, and fills the more refrangible end of the spectrum with lines and bands in which some of the flutings of hydrocarbon, cyanogen, and carbonic anhydride are to be distinguished.

There is a great difference in the relative intensities of the same lines in the gas from different minerals. Besides the case mentioned by Prof. Kayser of the yellow and green lines, 5876 and 5016, which vary in strength to such a degree as to render it highly probable that they represent two different elements, I have found many similar cases of lines which are relatively faint or absent in gas from one source and strong in that from another source.

Noticing only the strongest lines, which I have called "Intensity 10," "9," or "8," and taking no account of them when present in traces in other minerals, the following appear to be special to the gas from uraninite:—

4735·1
4658·5
4428·1
4424·0
4399·0
4378·8
4371·0
4348·4
4198·6
4189·9
4181·5
4157·6
3948·2
3642·0

The following strong lines are present in all the samples of gas:—

7065·5
6678·1
5876·0
5015·9
4922·6
4713·4
4471·5
4386·3
4258·8
4012·9
3962·3
3890·5
3888·5
3885·9
3819·4
3705·4

The distribution assigned to some of the lines in the above tables is subject to correction. The intensities are deduced from an examination of photographs, taken with very varied exposures; some having been exposed long enough to bring out the fainter lines, and some a short time to give details of structure in the stronger lines. Unless all the photographs have been exposed for the same time, there is a liability of the relative intensities of lines in one picture not being the same as those in another picture. Judgment is needed in deciding whether a line is to have an intensity of 7 or 8 assigned to it; and as in the tables I have not included lines below intensity 8, it might happen that another series of photographs with independent measurements of intensities would in some degree alter the above arrangement.

In the following table I have given a list of lines which are probably identical with lines observed in the chromosphere and prominences:—

Wave-lengths observed in [illegible].	Intensities.	Wave-lengths of chromospheric lines,[1] Rowland's scale.
7065·5	10	7065·5
6678·1	10	6678·3
5876·0	30	5876·0
5015·6	6	5015·9
4922·6	10	4922·3
4870·6	7	4870·4
4847·3	7	4848·7
4805·6	9	4805·25
4713·4	9	4713·4
4559·4	2	4558·9
4520·9	3	4522·9
4471·5	10	4471·8
4437·1	1	4437·2
4428·1	10	4426·6
4424·0	10	4425·6
4399·0	10	4398·9
4386·3	6	4385·4
4208·7	6	4208·5
4227·1	5	4226·80
4178·1	1	4179·5
3964·8	10	3964·0 H[2]
3948·2	10	3945·2 H
3913·2	4	3913·5 H
3888·5	10	3888·73 H
3819·4	10	3819·8 D
3733·5	5	3733·3
3705·4	6	3705·9 D

W. CROOKES.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

M[illegible] A[illegible] S[illegible], well known as the builder of the [illegible] tunnel on the Comstock Lode in Nevada, and now Mayor of San Francisco, has just offered the State University Regents thirteen acres of land within the city limits, on which to erect buildings for the affiliated colleges of the University. In addition to this, he will deed to the Trustee of the city thirteen acres adjoining, as a site for the Sutro library of over 200,000 volumes. The gift is valued at £300,000, and will be worth £400,000 when the contemplated improvements are made.

THE Clothworkers' Exhibition, awarded by the Oxford and Cambridge Schools Examination Board to the best candidate in physical science at the examination held for higher certificates, has been gained by T. W. Fagan, Denstone College, Staffordshire. The exhibition, which is of the value of £52 10s. a year, is tenable for three years by the holder as a non-collegiate student at either Oxford or Cambridge.

MR. W. M. GARDNER, Assistant Lecturer in Dyeing in the Yorkshire College, Leeds, has been appointed Head Master of the Chemistry and Dyeing Department of the Bradford Technical College.

THE Calendar of the Durham College of Science, Newcastle-upon-Tyne, for the session 1895–96 has just been published, and also separate prospectuses of the day and evening classes.

SIR A. ROLLIT asked the First Lord of the Treasury on Tuesday whether the Government intended, and when, to propose legislation in pursuance of the report of the Gresham Commission or the University of London. In reply, Mr. Balfour said that legislation will be impossible on the subject in the course of the present Session, and he was unable to say what action will be taken by the Government.

THE operations of the City and Guilds of London Institute are divided broadly into two branches, viz. the educational work of three London Colleges, and of the Technological Examinations. The new edition of the programme of the latter, including regulations for the registration and inspection of classes in technology and manual training, has come to hand. It is more bulky than any of the previous programmes of the examinations, which fact may be taken as an indication that the Institute is growing with the extension of technical education. The technical subjects in which examinations are held now number sixty-three. A practical examination for "electric wiremen" has been added, and a corresponding addition has been made to the syllabus for the preliminary examination in electric lighting. The syllabuses of several other subjects have been modified, and that in wood-work has been rewritten.

THE forty-second Report of the Department of Science and Art has just been received. A noteworthy point shown by the statistics contained in it is the diminution in the number of science schools, classes, and students under instruction, brought about by the abolition of grants for second class passes in the Elementary Stages of Science subjects. As compared with the previous year, the number of schools in 1894 had decreased by 152—from 2754 to 2602; the number of pupils had decreased by about 10,000—from 193,431 to 183,120; and the number of classes in different branches of science had decreased by 908—from 10,341 to 9433. This diminution is attributed to the changes in payments on results, "and also probably to the opening of numerous technical classes by the local authorities in different parts of the country, which have drawn away the students from the classes in pure science. The decrease in the number of schools and classes is owing partly to the same cause, and partly to the amalgamation of smaller schools, or to their absorption in the more prosperous and better supported schools in their neighbourhood, many classes in which instruction of a very elementary nature only had been given being at the same time closed." A determination has been made of the average ages at which students in the Department's science classes obtained successes in the Elementary and Advanced Stages. It was found that the average age in Day Schools for a student to obtain a first class elementary success was about 14, and for a second class Advanced about 15½, while in the evening classes the ages were respectively about 18 and 21. In addition to statistics, and information as to science instruction and technical education, the Report contains the reports of the work of the Geological Survey of the United Kingdom, and of the Committee on Solar Physics.

1 "A [illegible] Astronomy of [illegible]," by Dr. J. Scheiner, [illegible] 1894.

2 [illegible] D [illegible] H [illegible] are wave-[illegible] of the chromo-[illegible] (D) [illegible] Ha (H). [illegible] extend [illegible] of Lockyer [illegible] M[illegible] [illegible] between the wave-[illegible] in the chromo-[illegible] the [illegible].

SCIENTIFIC SERIALS.

American Journal of Science, August.—The earth a magnetic shell, by Frank H. Bigelow. This paper gives the vectors of the polar magnetic field at the earth due to the sun, together with certain deductions from their intensity and distribution. Unless the magnetic permeability of the interior of the earth is less than 1, which is highly improbable, the polar vectors obtained must be interpreted as stream lines flowing round an obstacle in the interior of the earth. In other words, the outer stratum of the earth is permeable to the external magnetic forces, while the nucleus is not; that is to say, the earth is a magnetic shell. The diameter of this impermeable nucleus is calculated at 6340 miles, and the thickness of the shell at 790 miles. The external polar field is concentrated in two belts, one of which is the auroral zone round the poles, and the tropical belt at the two tropics. It is a pity that most magnetic observatories are placed on the mid-latitude depression. Since both the magnetic and the electromagnetic vectors represent cosmical forces of the same type as gravitation, connecting the sun with the planets, they should be taken into account in general theoretical astronomy, or the celestial mechanics of the solar system. It is possible that certain irregular motions as yet unexplained may be accounted for on the basis of these additional forces.—On the velocity of electric waves, by John Trowbridge and William Duane. The apparatus used for photographing successive sparks whose images were thrown on the plate by a revolving mirror, was substantially the same as previously described; but the dielectric used was plate glass, and the terminals were made of cadmium. The average value for the velocity of electric waves travelling along two parallel wires was $3{\cdot}0024 \times 10^{10}$ cm. per second, a value which differs from the velocity of light by less than 2 per cent. of its value, and from the ratio between the two systems of electromagnetic units by even less.—On the distribution and the secular variation of terrestrial magnetism, by L. A. Bauer. The distribution and the secular variation appear to be closely related, they obey similar laws, and seem to be connected in some way with the rotation of the earth. The following are some of the laws traced by the author: The mean declination along a parallel of latitude is always westerly, the minimum occurring near the equator. The mean inclination along a parallel of latitude follows quite closely the law: $\tan I = 2 \tan \phi$ where I is the inclination and ϕ the geographical latitude. The minimum range in declination, and the minimum average secular change from 1780 to 1885 along a parallel of latitude occurred near the equator, the values generally increasing upon leaving the equator. The corresponding values in the case of inclination were maxima, and decrease upon leaving the equator.—Complementary rocks and radial dykes, by L. V. Pirsson. "Complementary rocks" are such that if the basic types are combined with the accompanying acid types, they give the composition of the main type of magma with which they are associated.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 1.—Dr. E. Lindon Mellus gave the results of experimental lesions of the cortex cerebri in the Bonnet Monkey. The experiments were confined to the left hemisphere, and consisted in the removal of minute portions of the cortex (generally about 16 sq. mm.) representing the centres for movements of the hallux and thumb, as well as several centres within the facial area. The animals recovered from the operation without any sign of sepsis, and were killed from ten to thirty-five days after the operation, the brains and cords hardened in Müller's fluid, and stained by the Marchi method. Numerous association fibres, both coarse and fine, connecting the lesion with the surrounding cortex, were found degenerated. These were always most numerous in the immediate neighbourhood of the lesion, and mostly distributed to the two central convolutions.

From lesions in the hallux centre degenerated association fibres were distributed to both central convolutions to the level of the inferior genu of the fissure of Rolando, to the parietal lobule, to the posterior portion of the superior frontal convolution, to the lobulus paracentralis, precuneus, and the gyrus fornicatus. Degenerate fibres crossed in the middle third of the corpus callosum and were distributed to corresponding portions of the right cortex, the degeneration on the right side being considerably less than on the left. In the lower levels of the left internal capsule the degeneration was scattered over the area of the middle third of the posterior limb, being somewhat anterior to its position in higher levels. From the posterior limb of the internal capsule most of the fine degeneration passed into the optic thalamus, while the coarse passed on into the crus, where it was found in the middle third. Many coarse degenerate fibres passed from the crus into the substantia nigra. At the decussation of the pyramids the tract divides, the larger portion crossing to the opposite lateral column, while the smaller goes to that of the same side. The amount of degeneration passing to the lateral column of the same (left) side varies from a third of all the degeneration in one case to about a twentieth in the others. In each case a few degenerate fibres remain in the left anterior column after the completion of the decussation. The amount varies in different cases, and is not apparently dependent on the proportion of degenerate fibres passing to the lateral column of the same side. The relations and extent of the degenerated areas remain unchanged throughout the cervical and dorsal cord. The degeneration in the crossed tract of each side is evenly scattered over its entire area, the two sides only differing in the density of the degeneration. In the lumbar region the degeneration in each crossed tract and in the left anterior column begins to go out, and, in the only case examined at that level, the degeneration had not all disappeared at the level of the third sacral root.

In lesions of the thumb centre (ascending parietal convolution just above the inferior genu of the fissure of Rolando) degenerated association fibres were distributed to the central convolutions from the border of the longitudinal fissure nearly to the fissure of Sylvius. To a less degree, but in varying amounts, degenerate fibres were traced to the posterior portions of the middle and inferior frontal convolutions, to the supra marginal and angular gyri, the upper or posterior portion of the superior temporal convolution, the precuneus and lobus quadratus and paracentralis and the gyrus fornicatus. Degenerate fibres crossing in the middle third of the corpus callosum were distributed to the corresponding convolutions of the right side, though less in amount and area of distribution. There was a remarkable variation in the size of the fibres distributed to the central convolutions of both hemispheres, being coarse above the level of the lesion and fine below, thus corresponding with the measurements made by Bevan Lewis of the corpuscles of the fourth layer of the cortex in this region. The arrangement and distribution of the degeneration in the posterior limb of the left internal capsule was the same as in lesions of the hallux centre, and there was the same passage of fine degeneration from the capsule to the thalamus. The amount of coarse degeneration passing from the crus to the substantia nigra was much greater than in lesions of the hallux centre, varying from a half to nearly the whole of the degeneration reaching the crus. In one case only was there a division of the degenerated tract at the decussation of the pyramids such as was observed in lesions of the hallux centre, and the amount of degeneration passing to the left lateral column was less than in either of the hallux cases. This was also the only case in which a few degenerate fibres remained in the left anterior column after the completion of the decussation. In two cases some degeneration was found in the right capsule and crus occupying the same position and following the same course as the degenerate fibres in the left capsule and crus, but its direct connection with the lesion could not be demonstrated. From the level of the seventh cervical root downward the degenerate fibres steadily and gradually disappeared, and at the level of the third dorsal root there were none left, thus confirming the results obtained by excitation of the nerve roots.

The lesions within the facial area were, with one exception, along the upper border of the fissure of Sylvius. The single exception was in the ascending frontal convolution near the inferior genu of the fissure of Rolando. In all these experiments the degenerate association fibres were mostly distributed to the central convolutions, but in some instances to the posterior portions of the middle and inferior frontal, the superior and inferior temporal convolutions, and the supra marginal gyrus. The degeneration in the corpus callosum was mostly in the anterior half of the middle third, and the distribution of degenerate fibres to the convolutions of the right hemisphere more nearly corresponded to that of the left than in lesions of the hallux or thumb centre. In all the lesions of the facial area the degenerations in the uppermost levels of the capsule were in the anterior portion, gradually moving backward in the lower levels until they were

found in the same position (the middle third of the posterior limb) as the degenerations resulting from lesions of the hallux and thumb centres. In this backward movement of the facial fibres in the capsule there is necessarily a level in which they envelope the genu, which would account for the fact that they are generally described as occupying that position. As in the other lesions, most of the fine degeneration passed from the internal capsule to the thalamus. In the crus the degeneration was scattered pretty evenly over the area of the middle third, exactly corresponding to the situation of the pyramidal fibres in the other experiments, and not occupying the position usually assigned to them, mesial to the pyramidal fibres. No degeneration was found in the accessory bundle to the fillet. As in the other experiments, degenerate fibres were found passing from the crus to the substantia nigra. The remaining degenerate fibres began to leave the left pyramidal tract at the junction of the pons and medulla, passing as single degenerate fibres to the facial nucleus of one or the other side. Below the level of the facial nuclei these fibres passed to the motor nuclei of the glossopharyngeus and vagus on both sides, the majority crossing the raphe to reach the nuclei on the opposite side. Occasional fibres were observed which apparently passed to some termination dorsal to these nuclei. This movement of degenerate fibres continued as far as the sensory decussation. A few degenerate fibres (probably thumb or finger fibres) remained in the pyramid and crossed in the decussation to the right lateral column, and disappeared in the lower cervical or upper dorsal region. In some of the facial lesions there were appearances of degeneration in the right internal capsule, but its connection with the lesion could not be demonstrated.

Academy of Sciences, August 19.—On matches tipped with explosive mixtures, by M. Th. Schlœsing. The author has experimented with a number of mixtures of substances with the view of finding a paste endowed with the properties of that mixture containing white phosphorus, and not having its poisonous character. The results show that it is necessary to use potassium chlorate, red phosphorus, ground glass, and glue or its equivalent, and that it is by no means a simple matter to find a perfect substitute for the paste used in tipping common matches.—On the storms and earthquakes in Austria during June, by M. Ch. V. Zenger. It is shown that during this period: (1) Solar activity has been very great. (2) Magnetic perturbations have been very ample and frequent. (3) Earthquakes and cyclonic storms of extraordinary violence have coincided with the appearance of numerous and brilliant meteorites, and with the passage of numerous shooting stars.—On equilateral hyperbolæ of any order, by M. Paul Serret.—On permanent deformations and the rupture of solid bodies, by M. Faurie.—On the conducting power of mixtures of metal filings and dielectrics, by M. G. T. Lhuillier.—Researches on the combinations of mercury cyanide with chlorides, by M. Raoul Varet. A thermochemical study on the combinations of mercury cyanide with the chlorides of sodium, ammonium, barium, strontium, calcium, magnesium, zinc, and cadmium. The solutions of these double salts do not give the isopurpurate reaction with a picrate at 30°, and hence the cyanogen remains wholly in combination with the mercury at this temperature. On boiling, however, there is evidence of interchange of a small proportion of cyanogen for chlorine.—Thermal researches on cyanuric acid, by M. Paul Lemoult. As in the case of phosphoric acid, the addition of each of three equivalents of alkali is marked by a different evolution of heat; the acid is a tribasic *mixed* acid.—Heat of combustion of some β-ketonic ethereal salts, by M. J. Guinchant.—Determination of heat disengaged in alcoholic fermentation, by M. A. Bouffard.—On the gum of wines, by MM. G. Nivière and A. Hubert.—On the migration of phosphate of lime in plants, by M. L. Vauhin.—Origin and rôle of the nucleus in the formation of spores and in the act of fecundation, among the Uredineæ, by M. Sappin-Trouffy.

BERLIN.

Physiological Society, July 5.—Prof. Munk, President, in the chair.—Prof. H. Munk spoke on contractures he had observed in monkeys after removal of the motor areas of the cerebral cortex.—Prof. Gad reported some experiments of Prof. Nicoladoni (of Athens), which had demonstrated the presence of fat granules in the pyloric gastric glands and in Brunner's glands.

July 10.—Prof. du Bois Reymond, President, in the chair. Dr. Schultz demonstrated micro- and macro-scopically the contraction of the unstriated muscle fibres of the stomach of Salamander. It was seen that the excised strips only contract when they are cut out in the direction of the long axis of the fibres, not when the fibres are cut through at right angles to their axis.—Dr. Rawitz had stained the lymphatic glands in the mesentery of *Macacus cynomolgus* by his "additive" method. He found the nuclei of the cells were generally placed excentrically, and contained a minute round chromatin patch. The linin network was marked by minute nuclei at the points of intersection and attachment. The structure of the plasma was quite indeterminate, but it appeared to contain a small round body, 2 to 3 μ in diameter, which stained somewhat deeply, and which he regarded as van Beneden's "attraction sphere."—Dr. Schultz had examined the optical properties of unstriated muscle-fibres of vertebrates in polarised light. It was found that although single fibres were not doubly refracting, a thicker layer of them was so quite distinctly. From this he concluded that the *single* fibres are in reality doubly refracting, but too feebly so to be perceptible. The double refraction became less during contraction, from which he concluded that, in accordance with von Ebner's theory, the anisotropic property of the fibres is due to differences in their internal tensions, the latter being greater in a transverse than in a longitudinal direction.

THE PENDULUM AND GEOLOGY.

Results of a Transcontinental Series of Gravity Measurements. By George Rockwell Putnam. *Notes on the Gravity Determinations Reported by Mr. G. R. Putnam.* By Grove Karl Gilbert. (Washington, U.S.A.: *Philosophical Society's Bulletin*, vol. xiii. pp. 31–76.)

SINCE the number of swings, which a pendulum of given length makes in a certain number of hours, depends upon the attraction of the earth at the place where it is swinging, it follows that, if an observer carries the same pendulum to different places, and notes the number of swings at each place he visits, he can by that means compare the force of gravity at the several places. If the earth were a smooth spheroid consisting of concentric shells, each of uniform density throughout, then gravity would have the same value at all stations situated on the same parallel of latitude. But if, as is the case in nature, there are mountains and elevated plateaus along the course followed by the observer, gravity ought to vary from its normal value, and in fact it is found to do so. Theoretically it is possible to calculate what variation of gravity at a given station ought to be caused by the altitude of the station, and the attraction of the neighbouring visible masses—*i.e.* of the mountain or plateau where the pendulum is swung, and of the rock masses round about, and when these disturbing causes are allowed for, and the corresponding corrections made, the value of gravity as deduced from the rate of the pendulum might be expected to tally with what it would be at the base level, supposing the mountains and all the surrounding masses carted clean away, and the smooth surface of the globe laid bare. This correction is termed reducing to the sea level, or to the mean level if the reference is made, not to the sea, but to some inland station. The question then to be answered for each station is, whether when this correction has been made, or, in technical language, when gravity has been reduced to the sea, or mean, level, does the reduction give the value which might be expected for the latitude? If it does not, this points to some deviation from regularity in the density of the earth's crust below the station, the nature of which may be inferred from the character and amount of residual discrepancy, when the reduction has been made. In this way it is that the pendulum becomes a kind of geological stethoscope.

In investigations of this kind, the elevated ground which forms the station is usually very much wider than it is high, so that, bearing in mind the law of the inverse square, it may be regarded as an extensive plain. If from local peculiarities it cannot be so regarded, compensatory allowances are made to bring it under that category. The effects of the station being situated on an elevated plateau are of three kinds, two of which cause gravity to appear smaller than it would appear at the sea level beneath the station, and one which causes it to appear greater. Of the two which make it appear smaller, the more important is, that the increased distance from the earth's centre causes the attraction of the earth as a whole to be diminished; the other, which is insignificant, and usually neglected, is that the increased distance from the axis of rotation increases the centrifugal force, which is opposed to gravity. The third effect, which causes gravity to appear greater than at the sea level, arises from the attraction of the matter of which the elevated plain, or mountain, is composed, for that may be regarded as an adventitious mass of rock, in excess of the sphere, placed beneath the pendulum. The reduction of the gravity observed at the station consists, therefore, in adding a correction equivalent to the diminution due to the elevation of the station, and subtracting a correction equivalent to the attraction of the mass of the elevated plain. If the reduction so made does not bring the observed value to agree with the value at the sea level, appropriate to the latitude of the station, there must be some geological cause present to account for the discrepancy.

It came to light in 1847, in consequence of the great trigonometrical survey of India, that, on approaching the range of the Himalayas within about sixty miles, the plumb-line, or vertical, was slightly deflected towards the mountains, so that it did not remain exactly perpendicular to the earth's surface. This was what might have been expected, because the great rocky mass would naturally draw the plumb-line towards it. But when the attraction of the mountains came to be calculated, it was discovered that, although their action was great enough to have caused a source of perplexity to the surveyors, it was nevertheless not so great as might have been expected. Clearly, then, some geological cause was latent, which required to be explained.

After some not very successful attempts at explanation by others, Airy, then Astronomer Royal, proposed in 1855 a solution of the difficulty which met the case. He assumed, as in those days was usually done, that the crust of the earth was comparatively thin, and rested upon a more or less liquid substratum, which in his paper in the *Philosophical Transactions* he called "lava." Then he showed that a great mountain mass would break the crust through unless it was supported by a protuberance beneath it, projecting downwards into a layer denser than itself. In short, it needed to be held up in hydrostatic equilibrium, much as an iceberg is supported in the ocean; and he explained how, under these circumstances, the observed deficiency of attraction of the plumb-line towards the mountains would be accounted for.

Although this observation upon the plumb-line was not a direct investigation of the force of gravity, it was nevertheless conducive to it, for the unexpected abnormality in the horizontal effect of mountain attraction rendered it probable that the same cause, whatever it might be, would produce some corresponding effect upon vertical attraction, *i.e.* upon gravity. It has been explained how the pendulum is the suitable apparatus for measuring gravity, and accordingly the pendulum was called into requisition to make more direct observations. At certain stations of the Indian Survey, of which the height and position had been already determined, the mean number of swings, called the "vibration number," was observed, which were made by the pendulum in twenty-four hours; and the force of gravity at the different stations was thus compared. The local attraction of the elevated mass on

which the pendulum stood, and the effect of elevation above the sea, were then allowed for, and the vibration number, when so corrected, was regarded as the vibration number for that station when reduced to the sea level. The pendulum used would have made 86,000 vibrations in twenty-four hours at the equator. It must therefore have been slightly longer than a seconds pendulum, which would make 86,400 in the same interval. The observations showed that there was a more or less marked deficiency of gravity over the whole continent of India, and that the deficiency was greatest at the most lofty stations. At Moré, 15,408 feet above the sea, the deficiency was enough to make the vibrations in twenty four hours twenty-four fewer than they ought to have been if the attraction of the mountain had produced its full effect. It was obvious, therefore, that some hidden cause existed which counteracted the attraction of the mountain, and this could have been no other than a deficiency of density in the matter beneath it. The conclusion is identical with that reached by Airy in connection with the deflection of the plumb-line, namely, that the Himalayan range is supported by a downward protuberance, projecting into a more dense substratum.

This mode of support, as already remarked, is similar to what is termed hydrostatic equilibrium. As applied to the support of the earth's crust American geologists have given to it the name "isostacy," which well describes the phenomenon.

During the past year an extensive series of gravity measurements has been carried out by the Coast and Geodetic Survey of the United States, by the use of the half-second's pendulum, a much smaller and more portable instrument for the determination of gravity than any hitherto employed. Observations were made at twenty-six stations, eighteen of which follow nearly along the 39th parallel of latitude; and these are particularly well adapted to throw light on important questions regarding the condition of the earth's crust.

> "This line of stations, commencing at the Atlantic coast, ascends to near the Appalachians, traverses the great central plain, gradually increasing in altitude from 495 to 6041 feet, then rises to the high elevation of the main chain of the Rocky Mountains, reaching an altitude of 14,085 feet at Pike's Peak, descends into the eroded valleys of the Grand and Green Rivers, crosses the summit of the Wasatch ridge, and finally descends to the great western plateau of the continent."

This series of gravity determinations affords an exceptionally favourable opportunity of helping to determine whether the support of the elevated regions traversed appears to be best accounted for by rigidity in the foundations on which they rest, so that, in spite of their weight and the largeness of the area occupied by them, they are prevented from sinking down into the material beneath; or, on the other hand, whether they are supported, as we have said that Airy suggested, namely by floating in a denser substratum, or, as the Americans say, by "isostacy," which is the same thing as hydrostatic equilibrium.

The general principle of the method pursued in reducing gravity to the sea level has been already explained. It consists in adding a correction equivalent to the diminution of gravity due to the elevation of the station, and subtracting a correction equivalent to the attraction of the mass of the elevated plain upon which the station may be considered to be situated. When these two corrections have been made, gravity so corrected would be the same as that appropriate to the latitude, or, as it may be termed, to the "computed value," unless there is some deviation from regularity in the density of the matter below sea level. The result proved that this was the case. For gravity so reduced turned out to be invariably less than that appropriate to the latitude. It was clear, therefore, that at these stations in America there was a deficiency in density beneath the elevated districts, just as had already been found to be the case in India. There could be no doubt that isostacy had a share in contributing to their support. The inquiry was now carried a step further. Did each mountain individually owe its support to a separate protuberance of its own beneath it, or was the mountainous region as a whole supported in that manner, each separate mountain owing its support to the strength of the crust on which it was a mere excrescence? The case might be illustrated by conceiving a number of logs of wood of different sizes. If these float side by side in water, the larger logs will stand the higher above the surface of the water; but each log will have a part immersed which will be its individual support, and this will be deeper for the logs which stand the higher. But if these logs are placed upon a raft, the support will be general, and derived from the support of the part immersed of the entire raft, and its depth will depend upon the aggregate weight of the logs. Nevertheless it need not dip deepest beneath the logs which stand the highest above the water, or above the floor of the raft.

The presumption was against each elevation being separately isostatically supported, because the deficiency in gravity, and therefore in density, was not found to be greatest precisely beneath the highest stations. To carry out the inquiry more fully, it was considered that, by omitting the part of the reduction to the sea level which takes account of the attraction of the mass of the plain (which would mean omitting to subtract the attraction produced by it), we should, as it were, transfer its mass to the subjacent parts, and so make up for the lack of density, and obtain the condition of uniform density below the sea level. There would then remain only the correction for elevation necessary. If this proceeding gave the value appropriate to the latitude under each station, it would show that the individual stations were seriatim in isostatic equilibrium. But the attempt failed. It was found that the attraction of the matter of the more elevated stations was not separately compensated by defect of density immediately below. The analogy of the detached floating logs did not hold good. It remained to inquire whether the series of stations was in isostatic equilibrium when considered as a whole—the case more nearly analogous to the raft. If this were so, gravity, when reduced to the sea level, would be uniform for the whole tract.

For this purpose a mode of reduction devised by M. Faye was adopted. The altitude of the country surrounding the station within a radius of 100 miles was reduced to a mean altitude, and the attraction of a plate of rock of thickness equal to the difference of altitude between this mean

plain and the station was allowed for, and it was found that this correction brought the gravity at each station much nearer to the computed value for the latitude than either of the previous methods. The conclusion was that, when large areas were considered, they were approximately in isostatic equilibrium. "The result of this series [of observations] would therefore seem to lead to the conclusion, that general continental elevations are compensated by a deficiency of density in the matter below sea level, but that local topographical irregularities, whether elevations or depressions, are not compensated for, but are maintained [supported] by the partial rigidity of the earth's crust." (Putnam.) "The measurements of gravity appear far more harmonious when the method of reduction postulates isostacy, than when it postulates high rigidity. Nearly all the local peculiarities of gravity admit of simple and rational explanation on the theory that the continent as a whole is approximately isostatic, and that the interior plain is almost perfectly isostatic." (Gilbert.)

It appears therefore that the crust of the earth is sufficiently thick and strong to carry such unequal loads as considerable mountains upon its surface without necessarily breaking through; but, when a large area is involved, it bends downwards into a denser material beneath, so that the crust and the load it carries are conjointly in approximate hydrostatic equilibrium.

O. FISHER.

SOME RECENT BOOKS ON MYCOLOGY.

British Fungus-Flora. A Classified Text-book of Mycology. By George Massee. Vol. iv. 8vo, pp. viii. 522. (London and New York: George Bell and Sons, 1895.)

Systematic Arrangement of Australian Fungi, together with Host-Index and List of Works on the Subject. By Dr. McAlpine, Government Vegetable Pathologist. 4to, pp. vi. 236. (Melbourne: Robt. S. Brain, Government Printer, 1895.)

Guides to Growers. No. 18. *Onion Disease.* By D. McAlpine. (Victoria: issued by the Department of Agriculture, 1895.)

MR. MASSEE is to be congratulated on the completion of another volume of his "British Fungus-Flora." There has been no complete work of the kind issued since the publication of M. C. Cooke's "Handbook of British Fungi" in 1871, and the knowledge of these obscure plants has advanced enormously since then. In the first three volumes the author treated the *Basidiomycetes* and the *Hyphomycetes*; the present volume takes up the large natural order of the *Ascomycetes*, and deals in turn with three families—the *Gymnoascaceæ*, the *Hysteriaceæ*, and the *Discomycetes*. The *Hysteriaceæ* form such a natural transition between the *Discomycetes* and the *Pyrenomycetes*, that it seems a pity Mr. Massee has not so arranged the families as to make them follow each other in the text-book; he has, however, very carefully pointed out the affinities of the different groups.

A general account of the *Ascomycetes*, their life-history, habitat, &c., is given in the introduction. The author agrees with Brefeld that sexual reproduction is unknown in this family. There is also some useful information about the best methods of collecting and preserving specimens, and of examining them. New descriptions have been written out for many of the plants, based in nearly every case on the author's own observations. Wherever it has been possible, he has examined the type specimens, or those specimens accepted as authentic in well-known *exsiccati*. It is impossible to over-estimate the value of such work. The descriptions are full and complete, and great care has been taken to give careful measurements.

The *Hysteriaceæ* have not before been worked up for Britain. Mr. Massee has not included *Acrospermum* in this family, nor in this volume. We await the next instalment of his work, to see where he will place it.

"British Discomycetes," by Mr. W. Phillips, has been for some time the standard work for that family. It was published in 1887, and there has been no reason for any material change in the way of treating the subject. The genera *Xylographa*, *Biatorella*, and *Abrothallus*, previously included among lichens, have been proved to be fungi, and are recorded, *Xylographa* in the family of the *Phacideæ*, *Biatorella* and *Abrothallus* in the *Patellariæ*.

The classification of the fungi is pretty well fixed as regards the natural orders, but no two systematists are agreed on the arrangement of genera and species. What characters are important enough to constitute a genus, is a question that each one answers in his own way. Phillips gave great importance to microscopic characters, but he was also largely guided by features visible to the naked eye or on slight magnification. He has comparatively few well-marked groups, and somewhat large genera with sub-genera. Saccardo laid much more stress on the differences between the species, and created new genera to represent deviations from the types, or revived old genera that had been sunk by systematists like Phillips. Mr. Massee goes even further; he retains nearly all the genera that had been kept up by Saccardo, and he has added in the *Discomycetes* eight genera revived from older authors, and five new genera, none of these being founded on new plants. Mr. Massee may be right in his views of classification, but the multiplication of genera and species, where that can be avoided, is much to be regretted. The matter has been admirably stated by Mr. Spruce in his "Hepaticæ of the Andes and Amazon," p. 73. "For a local flora," he writes, "or a limited area, too many genera will tend to produce confusion rather than precision, especially where several of the genera are monotypic; so that, on the whole, it seems desirable to make our genera as comprehensive as possible." There are several monotypic genera included in this volume, as for instance *Cubonia*, to which genus *Ascophanus Boudieri* has been transferred on account of its globose spores, those of *Ascophanus* being elliptical.

The task of classifying the *Pezizæ* is no light one; they are here divided into three large groups—*Glabratæ*, *Vestitæ*, and *Carnosæ*, under which the genera and species are arranged in a way that differs, in many instances, from that of every previous writer. The two first groups are familiar to us as the *Nudæ* and *Vestitæ* of Phillips. In the latter group the genus *Lachnella* has been dropped, and the species are dispersed and reclassified under *Erinella*, *Echinella*, *Diplocarpa*, *Dasyscypha*, &c. *Lachnella Cupressi* has been placed by itself in the genus *Pitya*, because the margin is free from the external hairs that are so marked a feature of this group, and because it

grows on conifers! In this group we also find *Geopyxis* Persoon emended Myc. Eur. i. p. 224 (not p. 42, according to both Saccardo and Mr. Massee): Persoon did not make *Geopyxis* a genus, although Saccardo also credits him with having done so; he published it as a division of *Peziza*, and Saccardo is the first who made it a genus, and therefore it ought to be *Geopyxis* Sacc. One of the species is the beautiful *Peziza coccinea* of old authors, transferred by Phillips to *Lachnea*, by Saccardo to *Sarcoscypha*, and now by Mr. Massee to *Geopyxis*. The division of the *Carnosæ* includes the genera *Peziza*, *Otidea*, *Humaria*, and others. A new genus, *Curreyella*, has been made to include *Peziza radula* and *P. trachycarpa*. Are we to assume that the Cuban species *Massea quisquiliarum* grows also in Britain?

In the family of the *Helvelleæ* there is much less alteration and rearrangement; but even there, two genera have been retained that were considered unnecessary by Phillips and Saccardo: *Cudonia* Fr., to contain *Leotia circinans*, which differs from others of the genus in the possession of filiform spores, and *Mitrophora* Lév., in which are placed two species of *Morchella*, *M. gigas* and *M. semilibera*. In these the lower half of the pileus is free from the stalk.

The numerous changes, however much we regret them, testify to the care with which Mr. Massee has treated the subject. He has omitted to mention one point of considerable morphological interest: that the abnormal many-spored condition of the ascus in *Tympanis* is due to budding of the original eight spores in the ascus.

The classified list of fungi, issued by Dr. McAlpine, has been compiled to assist vegetable pathologists in determining the diseases of plants due to these organisms. The knowledge of Australian fungi is as yet very incomplete, and we may expect the list to be largely augmented. M. C. Cooke's "Handbook of Australian Fungi" has served as a basis for the present work, and to it have been added the genera and species recorded by the more recent collectors and workers in this branch of botany. Australia possesses such a unique flora of the phanerogams, that we should have liked some indication of the fungi that belong exclusively to that country. The author has mainly followed the method of classification which has been adopted by Saccardo in his "Sylloge Fungorum." Dr. McAlpine retains the *Hyphomycetes* as a class by themselves, but describes them as imperfect *Ascomycetes*; this is hardly correct, for though many of them have been proved to be form-genera, others are unrelated so far as is yet known.

Besides giving us a list of fungi, Dr. McAlpine has drawn up some very instructive tables. The number of fungi recorded varies very much from colony to colony. Victoria heads the list with 1070 species, though we suspect the position of pre-eminence is due to the presence of Baron von Mueller, rather than to the abundance of fungi. Queensland records 1060 species, a large percentage of the whole due to the labours of an indefatigable worker, Mr. F. M. Bailey. Brisbane has 739 species, and New South Wales lags far behind with 406. There is much work evidently to be done before the localities are all worked out. The total number for Australia and Tasmania is 2294, as compared with 5040 recorded for Britain. The total number of species known to science is somewhere about 40,000. Dr. McAlpine has also prepared a host-index, which presents many points of interest. On *Casuarina*, that peculiar Australian tree, we find *Fomes igniarius*, a cosmopolitan species. *Eucalyptus* seems specially afflicted—leaves, bark, branches and trunk have all their separate fungal parasites. The *Compositæ* are hosts to but two, an *Æcidium* and a *Synchytrium*, evidently an incomplete account.

The *Agaricineæ* and *Polyporeæ* have received a much larger share of attention than the more minute forms of the *Discomycetes* and the *Pyrenomycetes*; Australian collectors give an account of but five *Nectrias* and two *Valsas*, but these forms are very easily overlooked. The *Phycomycetes* are also very sparingly represented; there are two *Peronosporas*, one on tobacco-leaves, the other on the onion. There is no record of potato disease, nor of salmon disease; we can only congratulate the colony on its immunity.

In addition to the authority and date for each fungus, Dr. McAlpine gives the locality in Australia, the habitat and a description in English of the species, but in no case does he indicate the characters of the genus; the list thus strikes the reader as being very imperfect, and the absence of all information as to the size of the particular plants renders it less useful than it might otherwise have been. We think he has vainly spent his strength in his attempt to provide an English equivalent for the scientific name of each fungus. Popular specific names have not been given even to flowering plants, such as the different kinds of *Myosotis* or *Crepis*, and such names are equally valueless in the case of fungi.

Dr. McAlpine has recently published, in "Guides to Growers," a most useful and practical account of the disease of onions caused by eelworms, with the best methods of cure. The worms live in the soil, and various dressings are recommended, suitable rotation of crops, or burning the surface of the land. This particular eelworm attacks the stems of plants, and in the case of the onion destroys the bulbs, leaving the roots unharmed.

A. L. S.

OUR BOOK SHELF.

The Climates of the Geological Past, and their Relation to the Evolution of the Sun. By Eug. Dubois. (London: Swan Sonnenschein and Co., 1895.)

THE first part of this essay consists of a brief and judicious summary of the geological evidence as to great changes of climate in past ages, while the second part is an attempt to explain the causes of such variations. Various well-known theories have been advanced to account for the phenomena, but none have met with general acceptance; a few years ago Dr. Neumayr wrote: "Most plausible and simple would it certainly be were the sun a variable star that at different periods emits different quantities of heat; but for this no proof is forthcoming." (NATURE, vol. xlii. p. 180.) The author of the present work seems to have adopted Dr. Neumayr's suggestion, but goes further and attempts to show that the postulated changes of solar radiation have actually taken place. In a general way, the fact that the sun must once have been hotter, has been frequently stated as a possible cause of the higher temperatures during early geological times, but a gradual cooling of the sun is insufficient to explain all the vicissitudes of geological climates. Basing his estimate on the relative proportions of stars of different spectroscopic types, the author considers that the sun has

passed about three-fifths of its star life, and that we cannot be far wrong in assuming for the past a maximum duration of about ten million years, and a radiation in the white-star stage twice as intense as at present. As a step towards the reconciliation of the life assigned to the sun by physicists and that demanded by geologists, it is suggested that in consequence of the higher temperature when the sun was a white star, denudation was carried on more vigorously, and animal and vegetable life developed more rapidly than has been supposed.

Notwithstanding that the author has approached the subject with an enlightened mind, he does not appear to have greatly advanced the explanation. For the production of changes other than those due to the progressive cooling of the sun, it is necessary to suppose that the sun is subject to periodical changes, and the chief argument brought forward in favour of this supposition is that the acknowledged eleven-yearly period of the sun renders it probable that there may also be periods of longer duration.

It is clear that such long-period changes are quite outside our range of observation, and the indirect evidence brought forward is unconvincing. We do know, however, that the variation which has been observed in stars resembling the sun is very rare and always slight.

Methodisches Lehrbuch der Elementar-Mathematik. Von Dr. Gustav Holzmüller. (Leipzig: Teubner, 1894–5.)

THIS is a text-book of elementary mathematics, showing the extent of knowledge required of the German schoolboy; and apart from the interesting presentation of the subjects in a manner far superior to anything we can show, the book is well worthy of translation as illustrating the difference in the standards of requirement of German and English schools; the knowledge exacted of the German schoolboy being about the equivalent of our B.A. requirements.

But then the German schoolmaster, although working to a much higher standard, can take his responsibilities lightly; he has merely to point out to his pupils that it depends entirely upon themselves whether they are to spend three years or only one under the civilising influence of the drill-sergeant.

The harder his pupils work, to escape with one year of military service, the higher the standard which the government inspector can exact for exemption; thus the paradoxical result is attained that the system of conscription tends ultimately to elevate the intellectual standard of school knowledge; but, on the other hand, the physical development of youth runs great risk of being stunted. Obviously there is no place in a German school, or French school either now, for the cricket, rowing, and football, which we now consider of equal importance with abstract studies. All Europe is now an armed camp, this country excepted; and the observant philosopher is doubtless beginning to draw inferences as to the comparative effect of the systems on the development of the human race.

Dr. Holzmuller's "Einführung in die Theorie der isozonalen Verwandschaften und der Conformen Abbildungen," 1882, is a well-known standard work, profusely illustrated with carefully-drawn diagrams, which emphasise many delicate points in the Theory of Functions in a manner much more convincing than arguments depending on a procession of analytical formulas; so also in this "Methodisches Lehrbuch," a plentiful supply of figures serves as a substitute for long algebraical calculations.

The author has made these elementary parts of mathematics more interesting and pleasant reading by historical notes and simple applications; and altogether the work is a great contrast to the dry bones we are accustomed to here; it would be well for our writers of school books to study the sentiment expressed in Dr. Holzmüller's preface: "Uns von der allzustarren Gebundenheit der Lehrpläne zu befreien." G.

LETTERS TO THE EDITOR.

Heights of August Meteors.

IN addition to the four or five meteors recorded last week in NATURE (vol. lii. p. 395–6), by Mr. Denning, as having been simultaneously observed at more than one station during this year's August-meteor period, particulars which have just now reached me of some observations of the Perseids made at Tring, in Herts, on the night of the 11th inst., show that two of the meteors seen and mapped here between 9.45 and 12 P.M. on that night, also had their apparent paths mapped simultaneously at a place at Tring, about nineteen miles due north from this point of observation. The base-line between the two stations is a rather short one for such comparative determinations, but as the recorded flights passed nearly overhead, and nearly from east to west across the line between the stations, the conditions for accuracy were very favourable in both the meteors' cases, and the apparent paths seem also, by the comparison, to have been mapped with much precision. They require, however, as usual, corrections of a few degrees at the beginning and end points to make them quite geometrically compatible.

Tring.—August 11, 9.53 P.M.; 1st magn.; left a long streak along a long path; 33°, from $332\frac{1}{2} + 39$ to $287\frac{1}{2} + 42\frac{1}{2}$; (corrected path, 35°, from 328 + 40 to 280 + 41). Duration, 2 or 3 seconds.

Slough.—August 11, 9.53 P.M.; 1st magn., white; 37° in 1·2 second, from 331 + 53 to 268 + 51; (corrected path, 35°, from $336 + 50\frac{1}{2}$ to 277 + 54). Left a bright white streak on its whole course for 3 seconds.

The observed tracks are 15° to 13° apart, nearly parallel, but slightly converging; and if made parallel, about 14° apart throughout, they indicate a radiant-point at the east-horizon (11° N. from E.), at 21 + 7, near μ and o Piscium, from very near which radiant-point the meteor was, no doubt, directed, as its long streak-leaving flight plainly enough denoted a very nearly horizontal motion. The resulting real path is from 77 miles over a point 4 miles north of Farringdon, in Oxfordshire, to 77 miles over a spot 3 miles E.N.E. from Uxbridge, in Middlesex. This course of 50 miles, with a duration of 1·2 seconds, gives the speed of flight $41\frac{2}{3}$ miles per second, the speed for meteors with parabolic motion from the same radiant-point (omitting a small addition for the earth's attraction) being $40\frac{3}{4}$ miles per second. In Mr. Greg's "General Comparative Table of Radiant Positions," as No. 106 of the list ("British Association Report," 1874, p. 333), a place at 22 + 5 is given as the average radiant-centre of a group of several meteor showers observed by Schmidt, in Athens (p. 321–2 of the same "Report"), in July, August, and September. It was thus from a very central direction of a rather notable autumnal group of meteor-showers in the neighbourhood of α Piscium, that this bright streak-leaving meteor seems to have proceeded. The corrections above applied to the recorded paths, although apparently considerable, are really only slight shiftings of the flights lengthwise; their original lines of direction, and hence their resulting radiant-point being left, as nearly equally as possible in both the paths, almost unaltered.

Tring.—11.3 P.M.; shot 12°, leaving a streak, from 345 + 58 to 325 + 53 (corrected path, 13°, from 343 + 58 to 322 + 52).

Slough.—11.4 P.M.; 3rd magn.; shot 10°, without streak, from 350 + 72 to 312 + 70 (corrected path, 10°, from 352 + 72 to $317 + 70\frac{1}{2}$).

The path corrections here are only small shortenings or extensions of the apparent tracks to bring their lengths into agreement (at distances apart then of 13° to 18°, in the right directions) without disturbing the path-directions, which diverge from 45 + 53, a point nearly coinciding with the usual radiant-point of the Perseids on August 10–11, at 44 + 56.

The concluded real path is from 67 miles over a point 5 miles west of Leighton, in Bedfordshire, to 53 miles over a point 3 miles west by north from Tring. The length and downward slope of the real path was $19\frac{1}{2}$ miles, from 45° altitude, 34° north from east. The time of flight of this small Perseid was not noted at either place of observation, but as it probably agreed with that of several similar short Perseids noted nearly overhead on the

same night, which varied with the lengths of path from about 0·5 to 0·7 sec., the velocity deduced would be between 39 and 27 miles per second, fairly agreeing with the real meteor-speed of the Perseids, which is 38 miles per second.

It would be interesting to learn if any observations were made elsewhere of a meteor seen at Tring at 9.32 P.M. on the 19th inst., descending from near the zenith at 317½ + 37, southwards to 320 + 15, which exceeded the fixed stars in brightness, and which was brilliant enough to attract the attentions of ordinary wayfarers there; so that with this observation of its path at Tring, its real course, and the position of its radiant-point in the northern sky might be determined. A. S. HERSCHEL.

Observatory House, Slough, Bucks, August 29.

Do the Components of the Compound Colours in Nature follow a Law of Multiple Proportion?

ON examining the data contained in Mr. Pillsbury's interesting and valuable *résumé* on colour measurements in the United States, by means of ordinates and abscissæ for the various colours on squared paper, it became at once evident from the parallelism of the diagonals which could be drawn that, although previously hidden, there was a numerical relation underlying them, and that probably the measurements would furnish an affirmative answer to the question printed at the head of this letter. Can it possibly be that those compound colours which occur with such profusion in nature are the result of simple colours being combined in definite multiple proportions? Can there be a law of multiple proportions here, similar to that which holds good in the domain of chemistry?

Let us see how far the data which Mr. Pillsbury gives support such a conclusion: they cannot from their paucity prove it. If we take all the foliage greens given, raise the percentage of black to 100 in each case, and proportionately increase or decrease the yellows and greens, then the amount of yellow in each case divided by the amount of green in each case will give a ratio which, the black being equal, may be said to represent in figures the colour of the particular foliage. Now what do we find on examining the resulting ratios? They are all divisible into groups of multiples of 2, which may be represented as in the last column of the table by 1-Y, 2-Y, 3-Y. It will be noticed that while the figure in the second decimal place is not exactly a multiply of 2, yet it tends very much in that direction.

	Black.	Yellow.	Green.	Yellow : Green.	Yellow.
Hemlock-Spruce	100	2·25	10·1	·22	1-Y
White Pine ..	,,	2·9	12·8	·22	
Apple ...	,,	6·25	3·75	·48	
Hornbeam	,,	6·8	15·3	·45	2-Y
Hickory	,,	5·3	11·1	·47	
White Birch	,,	6·8	14·1	·48	
White Oak	,,	9·3	14·3	·65	3-Y

Of course the conclusion reached cannot by any means be considered proved, as we do not know if the foliage greens were selected by Mr. Pillsbury purposely, or were merely the result of pure chance; but it would seem amply to repay further investigation, and I should be pleased to hear that Mr. Pillsbury could undertake it, or, if he feels unable, but would furnish me with the necessary material, I would try and undertake it myself.

As much stress is laid upon the commercial utility of this system of colour measurement, might I suggest that in all cases the simple colour of which there was the largest quantity should be taken as measuring 100? By this means there would always be one less number to recollect, write, or telegraph, than there are simple colours in the compound—no small factor when dealing with large quantities. F. HOWARD COLLINS.

[illegible], Edgbaston.

Transformation of Moulds into Yeasts.

Experiments carried out in Dr. Jorgensen's laboratory in Copenhagen, on the morphological relations of moulds and yeasts, are of great interest, and have an important bearing upon the study of the Japanese method of saké brewing, an investigation of which was made by the writer whilst in Japan, and the results of which were published by the National University of Japan in 1881.

In this process a mould is allowed to grow over the surface of steamed rice until the grains are firmly matted together by the fibres of the mycelium, and this product (*koji*), mixed with fresh steamed-rice and water, is placed in mash-tuns and slightly warmed. After a short time active fermentation sets in, resulting in the preparation of a liquid (*saké*) containing as much as 15 per cent. of alcohol. The question as to the origin of the ferment-cells was discussed in the memoir above referred to, and the conclusion was arrived at that there was no evidence to show that the mycelium underwent any change, but that the ferment-cells were derived either from the air, or from the vats, or from spores which had attached themselves to the surface of the mycelium. Microscopic drawings were given illustrating the appearance of the mash at various periods during the fermentation, and in these the mycelium was seen to preserve its original form to the end of the process. The feature upon which most stress was laid by those who asserted that the mould was converted into the ferment, was the suddenness with which the fermentation showed itself, of which fact there could be no doubt; but it seemed to the writer that there was a very simple explanation of this. The fermentation appears immediately after the warming of the mash, which has already been exposed to the air in shallow vessels at a low temperature for several days before being collected into a single vat. It is also allowed to stand in this vat for several hours before heating, during which time probably all the dissolved oxygen has been used up by the ferment. By heating, the temperature is then raised to about 25 C., a condition very favourable to the growth of yeast. Knowing how rapidly the yeast plant buds under such conditions, it does not seem necessary to invoke the transformation of the mycelium into ferment-cells to account for the sudden appearance of the fermentation.

The note (NATURE, August 22, p. 397) further says that Juhler found in his flasks in which the Japanese mould, *Aspergillus oryzæ* (called *Eurotium oryzæ* in the writer's memoir), was cultivated a growth of typical alcohol-producing saccharomyces cells. If there were spores attached to the surface of the mycelium, it seems necessary to know in what manner they were destroyed before the introduction of the mould into the culture flasks. It would also be interesting to have more details of the size of these cells, to ascertain if they correspond exactly with those found in the native Japanese fermenting vats. The size of the full-grown cells measured by the writer were on the average 0·0082 m.m. in their longest diameter—that is, between the dimensions of ordinary beer-yeast and wine-yeast.

Cardiff, August 24. R. W. ATKINSON.

IN reply to Mr. Atkinson's inquiries, we would refer him to Juhler's original communication on his experiments with *Aspergillus oryzæ*, to be found in part ii. of the *Centralblatt für Bakteriologie*, Nos. 1 and 9, 1895.

August 29. THE WRITER OF THE NOTE.

Mr. Seebohm on Middendorff's Credibility.

MR. SEEBOHM writes (*antea* p. 385): "There is no reason to believe that Middendorff ever found the eggs of the little stint. The eggs which he records as being those of *Tringa minuta* were probably those of *Tringa ruficollis* and possibly those of *Tringa subminuta*." To me these statements seem made in oblivion of the facts, and as some years ago I exhibited in London (*Proc. Zool. Soc.*, 1861, p. 398) one of the specimens on which doubt is thus thrown, I beg leave to show that there is no reason for believing that distinguished explorer to have been mistaken. The only eggs he records (*Sib. Reise*, II. ii. p. 221) are four, the parent of which he caught under his game bag. No other nest is mentioned, and this one was found on July 1, 1843, in the Taimyr peninsula, which is admittedly as well within the range of *T. minuta*, as it is outside of that recorded for *T. ruficollis* (*cf.* Palmén, *Vega-Exped. Vetenskapl. Jakttagelser*, v. tab. 4). Though not recognising these two birds as good species, Von Middendorff had carefully noticed (*tom. cit.* p. 222) the difference between examples obtained in the far East (Ochotsk) and in the high North (Taimyr), expressly stating that the latter agreed with Naumann's figure which undoubtedly represents *T. minuta* in summer plumage. As to *T. subminuta*, I am not aware of any evidence of its occurrence in the Taimyr, and by conjecture only can it be ascribed to that district; but the supposition that a single nest can have belonged to both *T. ruficollis* "and possibly" *T. subminuta*, is a masterpiece of conjecture wholly above my power of comprehension.

ALFRED NEWTON.

Magdalene College, Cambridge, August 23.

ON PHOTOGRAPHS OF THE MOON TAKEN AT THE PARIS OBSERVATORY.

QUITE recently some negatives of photographs of the Moon, taken at the Paris Observatory by MM. Lœwy and P. Puiseux, were exhibited at the Academy of Sciences.

The negatives have been carefully studied, enlargements made, and specimens sent to all the principal scientific societies interested in them. These enlarged copies are of great help in the study of the Moon, and have been the means of making clearer many uncertain points, for they allow every detail to be seen without difficulty. Their chief advantage, however, lies in the great expanse of surface which they embrace; many facts, hard to discover on the smaller negatives, have now been ascertained.

In their communication made to the Academy, MM. Lœwy and Puiseux gave an account of the results they have obtained in studying these photographs. Some of them are of great interest.

Considering, first, the Moon's surface, they note that its markings are of a less varied type than those of the earth, and its prominences are chiefly of a circular shape. By the way in which the Moon reflects, it is thought that its crust is of solid matter, similar to volcanic rocks. This agrees perfectly with Laplace's hypothesis, in which he states that the Moon was thrown off from the earth when the latter was in a nebulous state. The Moon's mean density scarcely surpasses that of the crust of the earth; its materials, judging exclusively from the exterior crust, are of a more uniform chemical composition. But although we might trace its history from the time in which it was thrown off from the earth, it is clear that all the facts rest on a very uncertain basis; it is scarcely probable that the Moon had the same appearance then it has now; it is only when the masses had become to a certain extent solid, that the surface-markings could have been formed which are now to be seen. A very long period must have elapsed between the nebulous state of the Moon and its present fixed condition, the process commencing, no doubt, by the union of the particles of scoriæ. Owing, however, to currents arising from various sources, ruptures must often have taken place, causing lines to be left on the parts which were not quite solid.

The various lines, which can be followed on the photographs, may be quite easily described. They are valleys between huge mountains. One of the largest is the valley of the Alps, to the west of Plato; another one between Herschel and Hipparchus, between Bode and Ukert; and one to the south-west of Rheita. It would be absurd to imagine them anything like the terrestrial valleys; they are almost perfectly straight, do not branch off at all, and keep the same width almost the whole length. There is no sign of what has become of the materials out of them, and when minutely examined, they appear to have flat bottoms; this fact seems to prove that they were once filled with some liquid which has dried up. As before stated, their origin is most probably due to currents, which must necessarily have developed in the mass of the moon when still fluid. These valleys are grouped about in various parts, and run parallel chiefly, especially near the equator, but they also go in other directions. There is nothing to show that the direction has remained the same.

So long as the revolution and rotation of the Moon were not performed in the same time, the tides must have produced very considerable change of level, which would hinder the crust from becoming solid. The scoria, therefore, would gradually form itself into larger and larger islands, which, however, might often have got broken up owing to constant collisions. Still gradually gaining in thickness, they eventually constituted the oldest part of the Moon, and at their expense the circular formations were formed which we now see. After a time banks of scoriæ of great length covered the Moon, leaving only narrow passages for circulation. Continual collisions destroyed the projecting parts, which facilitated the ultimate joining of the islands.

The fluid masses of a body like the Moon take part in the general circulation, but naturally have their tides under the influence of gravity. The combination of these two movements produces irregular rates in the floating masses, which more or less always impede their displacement. This irregular rate causes renewed collisions and rectilinear formations differing in direction from the first. After such various forces had been brought into play, it is not astonishing that the marks left are not absolutely regular and symmetrical. The parallel lines indicate the existence of similarly directed currents at the time the superficial solidification was going on. The lines running in different directions, indicate changes in the direction of those currents.

Let us now consider the result of a huge boulder of crust getting detached and falling. If falling on a slope, it would naturally slip down, and in the matter, not yet solid, form, as it were, a path; thus ultimately a valley would be made. This explanation applies itself more especially to the valley of the Alps, because of its very precise shape. If, therefore, these valleys are imperfect joinings of ancient ruptures, they must form, on the hard crust, lines of less resistance. The lines of craters are now easily explained, also the various holes in the furrows, which may be looked upon as explosion outlets.

If, on the other hand, they date from superficial solidification, their presence must have influenced the subsequent formations. Admitting that, under a part of the crust already thick, a diminution of pressure is produced, capable of producing a cavity, these changes might be brought about by the gradual cooling of the Moon, or by the movements of the interior tides. The cavities might take almost a circular form if the crust were homogeneous, having for the centre the point where the pressure was at a minimum. But if there are other ruptures and lines, they would probably form the boundary to the cavity. We notice that the polygon form is most frequent after the circular; in many cases, also, the furrows form tangents to the circles.

MM. Lœwy and Puiseux remark, finally, that it is not for them to say which of the hypotheses is correct; they merely wish to call attention to the immense help the enlarged negatives may prove themselves to be. Eventually, no doubt, they will be the means of making a map, which may show us that the surface structure of the Moon is very similar to our own.

We imagine that not every one will agree with all the opinions above expressed by MM. Lœwy and Puiseux, but it is clear that several important questions have been raised by the magnificent photographs we owe to their skill and industry.

UNSCIENTIFIC EXCAVATIONS IN EGYPT.

PROF. DR. G. SCHWEINFURTH has recently written a most interesting letter to the editor of *Die Zeitschrift für Aegyptische Sprache*. According to him, the time has arrived when a limit ought to be put to the energy of Egyptian excavators. Within the last few years there has been such a tremendous collecting of antiquities, that it has seemed to be the desire to leave nothing whatever for the next generation to discover. Our near descendants will, in all probability, not thank us for our want of patience; it may have totally different methods of research, and may bring opinions forward we have not dreamt of. If this be the case we shall, most probably, be blamed for having dis-

turbed so much, and shall be accused of "vandalism" under the mask of advancing scientific research.

There is no doubt that the excavations have been carried on too fast. The great museum in Egypt has no proper catalogue, and is arranged and filled up with things in a most unsatisfactory way; many objects have not even got the date when found. In this way, what would be treasures have become absolutely valueless on account of the carelessness of former officials, who constantly depended on each other, and, in many cases, on their memory, for the facts connected with objects found. This will always be the state of things unless the excavations are supervised by museums; for the haste with which they are carried on, does not allow time to work out the history properly. The things are merely brought under cover; they accumulate, and only short notices are written about them. It is for this reason that many noted things found have not been heard of till years afterwards; likewise, before the old treasures were properly examined, others have been dug out, particular attention being given to pretty things with which to ornament museums. Consequently, while search was being made for inscriptions, smaller objects were neglected, and many details overlooked.

Whereas formerly complaints were ever being made about the difficulty of obtaining permission to excavate, now the state of things is just the opposite. There is too much liberality; men are allowed to excavate, who have no knowledge whatever as to how to set about it, and have no serious object in view. Valuable things have been removed from the Fayûm, Heliopolis, and other places by quite uneducated people, and sold as market goods in Cairo. All this sort of thing makes the advancement of science a farce.

A natural consequence of this hasty digging, but a state of things greatly to be lamented, is the destruction of the ancient topography. The confusion caused is beyond description. It is very desirable that there should be an international inspection committee, which would insist on things being cleared up, and not allow the graves and tombs to remain open, with bones and limbs of the dead in them, which is so often the case.

Another deplorable fact is the absolute ignoring of objects connected with natural history. These objects require special care when being dug out, and also are more difficult to find. Their destruction greatly endangers the science of antiquity, and many an object, the value of which is now unknown, may in some future period be the key to some great problem. Likewise the bones of domestic animals are overlooked, although the many pictures of these animals help to make a study of them very interesting, and the remains of plants and flowers are similarly neglected, though these objects are the stepping-stones to the restoration of the ancient history.

JOSEPH THOMSON.

BY the death of Mr. Joseph Thomson, we have to mourn one of the foremost of contemporary African explorers. His loss is all the more sad, as it comes in what ought to have been the prime of his manhood. When we remember what Thomson has done, what a part he played in the exploration of British East Africa and in securing for England her supremacy on the Niger, it is difficult to realise that he has done it all before the age of thirty-eight. Joseph Thomson was born in Dumfriesshire, on February 14, 1858, and was the son of a quarry-owner. He was educated at Edinburgh, and early took a keen interest in African exploration, in which he first personally joined as assistant in Keith Johnston's expedition to the African Lakes. He left Dar-es-Salaam early in 1879, but before it reached its first objective point—Nyasa—its leader died. Thomson was then little over twenty-one years of age; but he rose to the occasion, took command, and single-handed carried the expedition to a triumphant conclusion. He explored the plateau between Nyasa and Tanganyika, and the western shore of the latter from its southern end to the Lukuga; there he added another to the pile of contradictory statements as to the relations of this river and the lake. He tried to work westward to the Upper Congo, but, owing to the hostility of the natives, he was compelled to return to Ujiji and back to the coast. This was Thomson's first expedition, and in some ways it was his best, for his scientific observations were then made with greater care and detail than in any of his later journeys. The following year he returned to East Africa to search for the coal reported on the Rovuma. Next year he was sent to Africa on the famous expedition, the story of which he so brilliantly told in "Through Masai-land." He left Mombasa in 1882 with a powerful caravan, fitted out by the Geographical Society, in order to determine whether there be a practical route across the Masai country to the Nyanza, to explore Mount Kenya, and to study the meteorology, ethnology, and natural history of the region traversed. After great difficulties with his men, he marched inland to Taveta, at the foot of Kilima Njaro. There he joined a powerful caravan under the famous slave-trader, Jumbo Kinameta, and together they traversed Masai-land to Lake Naivasha, going first along the route of Last, and then along that of Fischer. Thomson then turned to the east, and was the first European to set foot on the plateau of Laikipia and to see Kenya from the west. But the Masai were present in force, and Thomson had either to fight or retreat. He chose the latter alternative, and, contenting himself with a distant view of Kenya, under cover of night fled northward to Baringo. He explored this district, which he was the first European to reach, and then went on to the Nyanza, and back to the coast. His next expedition was up the Niger. His tact and patience in dealing with natives, here stood him in good stead, and rendered this expedition his most successful, for he returned with the treaties which gained for England practical supremacy in the Niger Basin. In 1888, with Mr. Crichton-Browne, he undertook a journey to south-western Morocco, materially correcting some previous descriptions of the structure of that country. He took a series of altitudes, and with characteristic acumen discovered for himself the divergences between the results given by aneroids and boiling-point thermometers; but it was equally characteristic that he did not follow up the subject, and contented himself with attributing it to the imperfection of his instruments. In 1891 he was sent by the British South Africa Company to annex the metalliferous region of Katanga. He was greatly hindered by the Portuguese, who fired upon his flotilla, and when he reached the frontier of Katanga he found that Captain Stairs's expedition had arrived before him, and secured the country for the Belgians. Thomson returned to England with his health ruined by his six African expeditions. Residence at Kimberley saved him for a while, but phthisis had taken too firm a hold to be dislodged, and after a lingering illness he passed away on August 2.

It is too early to attempt to estimate fairly Thomson's work as an explorer; but no one could follow in his footsteps without recognising how singularly keen was his topographic insight, how rapid his powers of observation, and how marvellously true were his instincts. His powers, in fact, amounted almost to genius. In his quickness of perception and his literary skill he reminds us of Burton, though without Burton's scholarship and colossal capacity for steady work. But Thomson's brilliant gifts had their dangers, and it is impossible to compare his work with that of some of his contemporaries, or even of some of his predecessors, without recognising that he was

sometimes as careless as he was capable, and that he rarely used his great abilities to the full. He belonged to the school of explorers who prefer rapid traverses and pioneer work, to scientific investigations and detailed surveys. He reminds us by his geographical work of Livingstone, and by his love of sport of Selous, rather than of men like Fischer, Schweinfurth and Junker. He was fonder of the field than of the library, and often did not, apparently, know which of his results were new, and which were known before. The thing of which he was proudest was that he had never taken the life of a native, for he had avoided hostilities owing to his tact and infinite patience, which was especially creditable to a man of such an impulsive temperament. His love of peace, however, was not due to any fear of war, for he was brave to recklessness. That he felt warmly, and could speak impatiently, was shown by his criticisms upon the management of the Emin Relief Expedition. In his most famous expedition it was unfortunate that he followed such a trained naturalist and learned ethnographer as Fischer, and was himself followed by such a laborious and skilled cartographer as von Höhnel. On the other hand, this journey was the one which showed Thomson's powers at their best; for he then had the fullest scope for the exercise of his tact as a leader of men, his dash and daring as an explorer, his enthusiasm as a sportsman, and the consummate skill with which he gained the affections of his men and the confidence of suspicious natives. The same qualities won him respect at home. He is described, by those who knew him, as singularly modest and unassuming. His frank sincerity and genial humour endeared him to a wide circle of friends, who devotedly cared for him in his long illness, and now mourn his early death.

J. W. GREGORY.

WILLIAM CRAWFORD WILLIAMSON.

WHEN the author of this article began the work for his "Einleitung in die Palæophytologie," he soon realised that it was quite impossible to produce such a book without an accurate knowledge of Williamson's collection of sections. He therefore wrote to Manchester and requested permission to make use of the collection. An invitation to Williamson's hospitable house was the immediate result. He there spent eight delightful and busy days, during which the host was never weary of demonstrating his specimens to his guest, who was astonished at their abundance, or of imparting to him the fullest information from his store of knowledge. The guest departed with feelings of the warmest respect and gratitude. In the course of the following years, however, he has often again had the privilege of returning to Manchester and London, and of knitting closer the bonds of reverence and friendship with him who is gone. The last occasion was in the spring of the current year, when the writer left with the conviction that it had been their last meeting. Williamson's death actually took place at Clapham Common, on June 23, when in his seventy-ninth year.

William Crawford Williamson was born at Scarborough, on November 24, 1816. His father, John Williamson, a gardener by profession, but by the bent of his mind a naturalist, and especially a geologist, was a zealous colleague of William Smith, who was attached to him both by friendship and by their common pursuits, and who spent two whole years, 1826–1828, under his roof.

Young Williamson's father encouraged his scientific tastes, even from his earliest days; his observational faculties were strengthened by frequent excursions; the association with Smith, and with the circle of active geologists of that fruitful period, influenced his boyhood, and left behind an effect which lasted his whole life. He has often told the writer about his geological and botanical rambles with his father and friends along the beautiful cliffs of the Scarborough and Whitby coasts. He had an extraordinary love for his more immediate home, and was proud to call himself a Yorkshireman.

Williamson's first publications, "On a Rare Species of *Mytilus*," and "On the Distribution of Organic Remains in the Lias Series of Yorkshire," appeared when he was only in his eighteenth year. About the same time he also contributed a considerable number of drawings to Lindley and Hutton's "Fossil Flora of Great Britain," a work which was completed in 1837, when he was twenty-one. In his later years he did not continue to work much at remains preserved as impressions, for his whole interest had become diverted to anatomical studies. One or two papers on *Zamia gigas* (now called *Williamsonia*), however, owe their origin to the material accumulated in those youthful days. The last and most important of these papers appeared in 1870, in the *Transactions* of the Linnean Society, vol. xxvi., under the title "Contributions towards the History of *Zamia gigas*."

Williamson's family was not much blest with this world's goods. He was therefore obliged to adopt some practical calling, and naturally chose the medical profession, for which he prepared, first at Manchester, while at the same time acting as Curator of the Natural History Museum there, and subsequently in London. In 1840 he became member and licentiate of the Royal College of Surgeons. Soon afterwards he settled in Manchester as a medical man, and remained there over fifty years, carrying on for a long time an extensive practice. In addition to this the professorship of Geology and Natural History at the Owens College was conferred on him in 1851, an office which he administered, in its full extent, for many years. In 1872, however, he handed over the geology to Boyd Dawkins, and from 1880 onwards gave up the zoology, and confined himself to botany. This he continued to teach down to 1892, when his decreasing bodily strength compelled him to retire altogether. He then removed to London, in order that with the aid of the greater facilities there offered he might the better advance the scientific work, which he was still zealously pursuing. Here, after three more years, he too soon ended a life of which one may certainly say, with the Psalmist, that its strength was labour and toil.

For medical practice and professorial duties, though strenuously and most conscientiously carried on, did not satisfy Williamson's mighty power of work. Concurrently with these occupations, a constant flow of scientific production went on, the many-sidedness of which is scarcely conceivable to the present generation. Not only did he write articles in medical journals, which lie beyond the scope of the present notice, he also continued to work with the greatest zeal at zoology, botany, and, above all, geology and palæontology, as is testified by his numerous publications large and small.

From his youth upwards, Williamson had been much occupied with the investigation of fossil fishes, and in the latter half of the thirties, and beginning of the forties, he wrote various memoirs on this subject. His studies of lower organisms gave rise to the works on *Campylodiscus*,[1] on *Volvox Globator*,[2] and on *Foraminifera*, the last and most important of which, embracing the whole of his researches on the subject, was published by the Ray Society in 1858, under the title of "The British Foraminifera." These writings have received due acknowledgment in the works of Carpenter and Bütschli.

In 1833 the remarkable work by Witham, of Lartington, appeared, in which the study of the internal structure of carboniferous fossil plants was entered upon for the first time, with the help of the thin ground sections

[1] "Annals of Nat. Hist." vol. i., 1848.
[2] *Memoirs* of the Manchester Lit. and Phil. Soc., vol ix. 1851, and *Transactions* of the Microscopical Soc., vol. i., 1853.

invented by Nicol. This work laid the foundation of our knowledge of the structure of the *Lepidodendra* and *Stigmariæ*, and Brongniart then applied the new method, with the most brilliant success, to the investigation of *Sigillaria*. Williamson also soon attained brilliant results by its aid, studying the shells of Foraminifera, and the scales and teeth of fishes. Two papers, published in the *Philosophical Transactions* (1840 and 1851), and considered excellent by competent judges, were the result.

Naturally, the study of fossil plants, which had been so successfully begun, was not neglected, whenever such material could be obtained in the proper state of preservation, which at that time was not easy. Williamson's first attempt of the kind, the precursor of the whole palæobotanical literature which he created, was the paper "On the Structure and Affinities of the Plants hitherto known as *Sternbergiæ*," in which the *Sternbergiæ* were identified as medullary casts, which had been surrounded by an Araucarian wood. As already mentioned, however, the material for an extended use of the method was at that time still wanting. Then, just at the right moment, came the discovery of the calcareous nodules, enclosing vegetable remains, in the Ganister beds of the coal-fields of Lancashire and Yorkshire. The investigation of the treasures thus revealed was first taken in hand by their discoverer, Binney himself, and subsequently by Carruthers and Williamson. The latter first began with works on the Calamarieæ, three of which appeared in rapid succession from 1869 to 1871. They are: "On the structure of an undescribed type of *Calamodendron* from the upper coal measures of Lancashire"; "On a new form of Calamitean strobilus"; and "On the organisation of an undescribed verticillate strobilus from the lower coal-measures of Lancashire."

As was necessarily the case, material now began to accumulate in Williamson's hands, and he enjoyed the active co-operation of various zealous collectors. Then, in his fifty-fifth year, he began the great series of memoirs which mark the culminating point of his scientific activity, and which will assure to him, for all time, in conjunction with Brongniart, the honourable title of a founder of modern Palæobotany.

In the course of the following twenty years, nineteen memoirs of this series appeared in the *Philosophical Transactions*, under the general title "On the Organisation of the Fossil Plants of the Coal-measures." They all contain exclusively his own observations, made entirely on material from the British coal fields. It is a gigantic work, which by itself alone would form the abundant fruit of a man's whole life. It was supplemented, however, by various other contributions to the same subject, published in the *Memoirs* of the Literary and Philosophical Society of Manchester, the *Annales des Sciences naturelles*, and the *Annals of Botany*. During the same period, in 1887, also appeared Williamson's exhaustive "Monograph on the Morphology and Histology of *Stigmaria ficoides*," which will long form the basis of our knowledge of these fossils.

The recognition by palæontologists and botanists of the full importance of these works of Williamson's, has been of course a slow and gradual process. This was really due to external circumstances. In the first place, Williamson found it necessary, as the material in his collection, and his own experience increased, to return repeatedly in his later memoirs to plant remains which had been dealt with in the earlier parts. Consequently, if one wish to obtain an idea of any group, it is always necessary to study several of these treatises simultaneously. This, however, presents great difficulties, except to those who possess separate copies. For the reader stands helpless before a pile of sixteen volumes of the *Philosophical Transactions*!

On the other hand, there is another point which must be taken into account. Williamson's method of anatomical description, clear as it is, bears the stamp of the scholastic ideas of a past time. For this reason it is only understood with difficulty by the botanists of the present day, and must often first be translated into the form now customary. This is laborious, and has stood greatly in the way of the rapid diffusion of his results.

Williamson himself was fully conscious of these drawbacks, and finally, in order to remedy them, he began a new series of memoirs, in conjunction with Dr. Scott, the object of which was to present a connected and systematically-ordered account of the results obtained, clothed in the language of modern anatomy. The first memoir of this series appeared in 1895, in the *Philosophical Transactions*, and treats of the Calamarieæ and Sphenophylleæ. Two further papers are already completed, but he was not spared to see them published.

The basis of all Williamson's labours in fossil botany is, of course, the collection of slides which he left, containing some thousands of preparations. It is unique of its kind in the world, and of the greatest importance, for it contains the evidence for all the innumerable special observations recorded in his works. Like Willdenow's herbarium or Lindley's collection of orchids, it will always remain an invaluable source of information, to which palæontologists from all sides must resort. Its owner was aware of this, and so also is the author of this notice, who may boast that he knows the collection as scarcely any one else does. It was through him that Williamson decided to prepare and distribute, in a printed form, a detailed index, giving exact references to the individual preparations, and the places where they are cited in the memoirs. This was necessary, for the multitude of preparations often made it very laborious, even for the owner, to look out a particular section to demonstrate some special fact. This work was taken in hand about 1890, and has considerably increased the usefulness and value of the collection to posterity. Three instalments, and those the most important, have already appeared under the title, "General Morphological and Histological Index to the Author's Collective Memoirs on the Fossil Plants of the Coal-measures." Only the Cordaiteæ, the Gymnospermous seeds, and a number of fossils of doubtful affinity, are still wanting. We may, no doubt, ultimately look for a synopsis of these from the hand of a friend, so as to complete the entire work.

If we now consider the contents of the palæobotanical literature created by Williamson during the last twenty-five years of his life, we find that it consists, first of all, of the most minute description and reconstruction of all those types of plants which took part in the formation of the coal-beds of Great Britain. He abstained on principle from concerning himself with non-British material. We have acquired from him the most exact knowledge of the structure of the Calamarieæ, the Lepidodendreæ, the Sphenophylleæ, the Ferns, and Lyginodendreæ. As regards several of these groups, it is true, he had before him fairly detailed investigations by previous observers, but in other families, especially the Calamarieæ and Lepidodendreæ, he himself laid almost the whole foundation of our knowledge. He showed that both groups are, as regards their fructifications, indubitable Archegoniatæ, but that they possessed, like our recent Gymnosperms, a secondary formation of wood from a cambium; he taught us to recognise, in the Stigmariæ, the subterranean organs of the Lepidodendreæ and Sigillariæ; he reconstructed in the genera *Lyginodendron* and *Heterangium*, described by him, a type of plant which, by its characters, occupies an intermediate position between Filicineæ and Gymnosperms, especially Cycadeæ. It thus can find no place in the system of recent plants, but represents a direct derivative of the unknown ancestral stock from which the two groups still living have also sprung. In connection with this type, Renault's Poroxyleæ have since turned out to be their

later Permian relations, while the Protopityæ of the Culm are more ancient allies, with similar characteristics. We thus learn how far back we must go, in the series of geological formations, in order to meet with the last traces of the common ancestors of those classes in the vegetable kingdom which are now living.

By his discovery of Archegoniate plants with secondary growth, Williamson however came into collision with the doctrines of Adolphe Brongniart, otherwise so highly reverenced by him, who held this character to be an absolute criterion of the Phanerogams, and denied the possibility of its occurrence in other classes of the vegetable kingdom. Hence a literary feud arose between Williamson and B. Renault, Brongniart's distinguished pupil. The latter endeavoured to prove that Williamson was in error in the identification of his *Lepidodendra*, that they were really *Sigillariæ*, and together with the latter belonged to the Gymnosperms, while the truly Archegoniate *Lepidodendra* were destitute of any secondary growth. The answer was not long in coming; proof was heaped on proof, until ultimately the real state of the case was made completely clear. In all essential points victory was on the side of our author. Other subsidiary differences respecting *Stigmaria*, the Calamarieæ, &c., require no more than a mention here.

It was thus made evident by Williamson that cambial growth in thickness is a character which has appeared repeatedly in the most various families of the vegetable kingdom, and was by no means acquired for the first time by the Phanerogamic stock. This is a general botanical result of the greatest importance and the widest bearing. In this conclusion Palæontology has, for the first time, spoken the decisive word in a purely botanical question. The result has proved well worth the great trouble and labour which had to be gone through in order to attain it.

It would be difficult to conceive a more magnificent monument to Williamson than one which he himself set up at Manchester, in one of the halls of the Owens College Museum.

In the year 1887 there was discovered in a quarry near Bradford, a gigantic petrified tree-stump, which, when carefully exposed, was found to run out at the base into a widely-spreading system of ramifications of a Stigmarian character. In the quarry this precious relic, like many others before it, would in a very short time have fallen a victim to destruction by weather and the hand of man. Williamson, however, acquired it by purchase, had it carefully subdivided into numerous pieces, and brought it home safe and complete to Manchester. This was not accomplished without the greatest personal exertions and a considerable expenditure of money (to which several friends contributed), for there were whole waggon-loads of material to be removed. Then the first thing which had to be done was to secure from the University authorities the necessary space for erecting the fossil. This was not an easy matter, and great opposition had to be overcome, as we can easily understand on looking at the specimen, which measures over 29 feet in diameter.

Finally it was fitted together, piece by piece, and fixed in its natural position, resting on a massive pedestal of brickwork. The fiery youthful zeal of a man already over seventy, overcame all the difficulties that arose. People were astonished at the unusual development of energy which this *Stigmaria* had caused, and gave it, in good-humoured jest, the name of "Williamson's Folly." "Williamson's Folly" may now be reckoned among the sights of England, and Manchester may be proud of possessing it, for it represents a last gift, worthy of all honour, from the deceased, to the place which for so many years was his home and the scene of his activity.

The author of this notice, who only knew Williamson during the last years of his life, must not attempt to picture to those who lived with him his kindly and benevolent nature, which always retained the freshness of youth, or his simple character. That would be a work of supererogation, for the whole of scientific England knew and respected him, and wherever he went he was a welcome and honoured guest. The writer can only report, in all brevity, on the work of Williamson's life, and when asked to undertake this, it was with pleasure that he took up his pen for that purpose. Solms-Laubach.

NOTES.

The resignation of Dr. Albert Günther, F.R.S., of the post of Keeper of Zoology at the Natural History Museum, South Kensington, is announced. Dr. Gunther has occupied for over thirty years the position he now vacates.

The "Swiney" Lecturer this year is Dr. J. G. Garson, who will take as the subject of the twelve lectures he purposes giving, "The Geological History of Man." The lectures, admission to which will be free, are to be delivered in the lecture theatre of the South Kensington Museum on Mondays, Wednesdays and Fridays, at five P.M., beginning on Friday, October 4.

We have to record the death of two prominent members of the medical profession abroad, viz. Dr. Pasquale Landi, Professor of Clinical Surgery successively in the Universities of Siena, Bologna, and Pisa, and Dr. Texier, Professor of Internal Pathology in the Medical School of Algiers.

Mr. Charles Mitchell, whose death, at the age of seventy-five, occurred on August 22, was a well-known engineer and shipbuilder. He founded the Walker shipbuilding yard on the Tyne, a yard which under his guidance developed into one of the largest in the country. In 1882 it was merged into the Elswick Company of the present Lord Armstrong, and up to the time of his death Mr. Mitchell practically superintended the whole of the shipbuilding work of the Company.

The *Athenæum* says that during the autumn of this year a monument is to be unveiled at Osteel, in East Friesland, in memory of the discoverers of the sun's spots, David and Johann Fabricius. The site chosen is the place in the cemetery where the grave of the elder Fabricius was discovered about nine years ago.

We are informed by Prof. John Milne, that communications respecting the *Transactions* of the Seismological Society, and the *Seismological Journal*, may be addressed to him at Shide Hill House, Shide, Newport, Isle of Wight, at which place a small station has been established to record earthquakes having their origin in distant localities, and other unfelt movements of the earth's surface.

The annual general meeting of the Federated Institution of Mining Engineers will be held in North Staffordshire, at Shelton, Stoke-upon-Trent, on September 18 and 19, when papers on "The Depth to Productive Coal-measures between the Warwickshire and Lancashire Coal fields," "Gold-mining in Nova Scotia," "The Use of Steel Girders in Mines," "Economic Minerals of the Province of Ontario, Canada," and "The Blasting Efficiency of Explosives" are expected to be read, and a discussion of various papers which have already appeared in the *Transactions* of the Institution may take place. A number of excursions are also arranged.

The fifth quadrennial meeting of the International Congress of Otology will take place at Florence, under the presidency of Dr. V. Grazzi, from September 23 to 26. Various discussions will be opened by Dr. Barr of Glasgow, Dr. Gellé of Paris, Prof. Gradenigo of Turin, Prof. A. Politzer of Vienna, and Dr. Secchi of Bologna; and there are in the complete programme,

which [illegible] just been issued, the titles of no fewer than fifty-nine original communications to be brought before the meeting. It is hoped that British otology will be well represented, as it is intended to invite the next congress to meet in London, either in 1898 or 1899. Full particulars as to terms of membership, routes, hotels, &c., may be obtained from Dr. St. Clair Thomson, 28 Queen Anne-street, W.

AN International Congress of Technical, Commercial, and Industrial Education is being organised by the Société Philomathique of Bordeaux, and is to be held at Bordeaux from September 10 to 21. The programme is, we understand, a full one, and contains many items of interest and importance.

A FEATURE of the annual meeting of the Yorkshire Naturalists' Union, which is to take place at York on October 30, will be an exhibition of specimens, photographs, &c., showing work done during the past year in all departments of the Union. It is requested that all members who intend to exhibit will communicate direct with the Local Secretary, at the Museum, York, on or before October 21.

THE various medical schools will be reopened at the beginning of October, and at most of them introductory addresses will be delivered to the students. On October 1, at St. George's Hospital, the speaker will be Mr. George D. Pollock; at the Middlesex Hospital Dr. W. Julius Mickle, and at the Westminster Hospital Dr. Monckton Copeman. At the latter institution Viscount Peel will distribute the prizes. The introductory address at University College will be delivered by Prof. J. Rose Bradford, and the annual dinner of old and present students will take place at the Hôtel Métropole on October 1, under the chairmanship of Sir Richard Quain, Bart. Mr. A. P. Laurie will give the address at St. Mary's, and the annual dinner will be held the same evening at the Holborn Restaurant, Mr. Malcolm Morris occupying the chair. At St. Thomas's Hospital the prizes will be distributed, on October 2, by Sir Edwin Arnold, K.C.I.E. At Guy's there will be no formal introductory address, but on the evening of October 1 Mr. J. De'Ath will read a paper at the opening meeting of the Physical Society, on "Our Profession, our Patients, our Public and our Press." The annual dinner will take place in the Club Dining Hall, Dr. Pye-Smith in the chair. At the Yorkshire College, Leeds, Prof. D. J. Leech will, on October 1, distribute the prizes and deliver an address. Prof. Victor Horsley is announced to speak at the Sheffield School of Medicine, Mr. Jonathan Hutchinson at University College, Liverpool, and Prof. I. H. Napier at St. Mungo's College. At Mason College, Birmingham, Prof. Percy Frankland will deliver the address, taking as his subject "Pasteur and his Work."

THE Council of the Institution of Civil Engineers has issued a list of suggested subjects for papers during the session 1895–96, for which the undermentioned prizes may be awarded: (1) The Telford Fund, left "in trust, the interest to be expended in annual premiums, under the direction of the Council." The bequest (with accumulations of dividends) produces a gross amount of £235 annually. (2) The Manby Donation, of the value of about £10 a year, given "to form a fund for an annual premium or premiums for papers read at the meetings." (3) The Miller Fund, which, with accumulations of dividends, realises nearly £140 per annum. Out of this the Council has established a scholarship, called "The Miller Scholarship," and is prepared to award one such, not exceeding £40 in value, each year, and tenable for three years. Competitors for this scholarship must be under the age of twenty-five years. (4) The Crampton Bequest of £500, the annual income of which amounts now to £13 14s., [illegible] foundation of "The Crampton Prize," for "presentation to the author of the best paper on the Construction, Ventilation, and Working of Tunnels of Considerable Length, or failing that, then of any other subject that may be selected." (5) The balance of the Trevithick Memorial Fund of £100 0s. 9d., the interest of which is £2 15s. a year. The list of suggested papers, although not exhaustive, is far too long for us to print, but may be had, with further information, upon application to the Secretary of the Institution.

THE Royal Academy of Medical, Physical, and Natural Sciences of Havannah, at a meeting held on April 28, decided to offer amongst other prizes, mostly for medical essays, one—the Cañongo Prize, value 250 dollars in gold—for the best essay on "The Pharmacological Study of the Fluid Extracts." The competition, which is open to any person whether belonging to the medical profession or not, will be closed on March 19, 1896, by which date all papers must be sent in, written in French or Spanish, and sealed, with a motto on the internal envelope, and in another envelope bearing the same motto the author's name and address. The adjudication will take place on May 19, 1896, when the prizes will be distributed to the successful competitors. Further particulars may be obtained by writing to the Secretary, Dr. Vicente de la Guardia, Havannah.

UNDER the active presidency of the Earl of Derby, a vigorous effort is being made by the British Dairy Farmers' Association to give a helping hand to one of the most important branches of agriculture, dairy farming, and its allied industry of poultry raising. At the twentieth annual London Dairy Show, to be held at the Royal Agricultural Hall in October next, prizes to the value of £2515, in addition to 142 gold, silver, and bronze medals, are offered for competition in 451 different classes, in many of which a keen contest is already assured.

AN interesting memoir has been recently published by Dr. Max Müller, on the effect of fever temperature upon the growth and virulence of the typhoid bacillus. In view of the conflicting opinions which have from time to time prevailed on the manner in which a high temperature affects the agent of infection in cases of typhoid fever, these results are of some considerable practical interest. Thus in 1882 we find Jorgensen ventilating the idea that the development of the morbific material in the system in cases of typhoid fever might be retarded by greatly reducing the temperature of the body, whilst other authorities have as confidently stated that the feverish rise in temperature was capable of destroying the typhoid organism, or, at any rate, hindering its development. Both of these opinions are based on very slender experimental evidence. Dr. Max Muller has carried out a series of researches in which he has carefully recorded the growth of the typhoid bacillus at various temperatures, and he states that when preserved at about 40° C. this microbe takes five minutes longer to proliferate, or produce a new generation, than when it is kept at a temperature of from 37·5° to 38·0° C. respectively; that is to say, in the absence of all adverse circumstances, under the most favourable conditions, as many as forty-five generations of typhoid bacilli may proceed in one day from a single parent bacillus at the *normal* temperature of the body, whilst at about 40° C. thirty-nine such generations may be elaborated. In considering these appalling figures it must, however, be remembered that such an uninterrupted multiplication of the typhoid bacillus does not necessarily take place in the human system; the conditions which surround it in the latter case are of a far more complicated and subtle character than those which obtained in Dr. Müller's laboratory culture-tube! But these results show that a fever temperature of about 40° C. is not able to destroy the typhoid bacillus, or to affect its growth to any considerable extent; even higher temperatures of 41·5° to 42·0 C. were also incapable of annihilating this microbe, and typhoid bacilli kept for sixty-two days at 42·0° C. showed subsequently no abatement of their vitality. As regards

the effect of such temperatures on the virulence of the typhoid bacillus, Dr. Müller states, but only as the result of very limited experiments, that he could detect no difference in the behaviour in this respect of those kept at 37° and 40° C. respectively.

A MODIFIED centesimal system of subdividing time and angular measures is advocated by M. H. de Sarranton, in the *Revue Scientifique*. He proposes to retain the hour as a fundamental unit of time, on account of its universal acceptance, its convenience, and the hopelessness of the task of altering it. But the hour should be divided into 100 minutes, and the minute into 100 seconds. Thus each new minute would be three-fifths of an old minute, or thirty-six seconds, while the new second would be a little over a third of the present second. Two of the new seconds would cover the time of a brisk step, like the accelerated pace used in the French army. The new second is the time taken by one semi-vibration of a simple pendulum 12·9 cm. long. Time could then be consistently expressed in hours and decimals. Thus 8·3348 h. might be read 8 hours 33 (new) minutes 48 (new) seconds, and calculations involving time would be much simplified. Clock and watch dials would be subdivided into hours, as usual, but the smaller divisions for the minute and seconds hands would be hundredths of the circle instead of sixtieths, and every tenth division would have to be slightly marked. For angular measurement, M. de Sarranton proposes 240°, subdivided into 100 minutes of 100 seconds each, so that they could be converted into hours by shifting the decimal point one place to the left.

A FEW particulars of the new mouth of the Vistula are given in the *Globus*. It was made by regulating the old branch going into the Baltic, which was straightened and shortened from ten miles to four and a half, while the channel was broadened by shifting the dyke on the left bank six miles to the west. At the same time, the Danzig branch was cut off by a lock. This useful piece of work will not only make the Vistula more accessible, but will prevent the disastrous floods which caused far-reaching destruction in winter and spring, near the mouth of the river. The work cost a million pounds, half of which was borne by the districts concerned, and half by the German Treasury.

THE current number of the *British Medical Journal* has a note on the vision of School Board children, based upon a report of Dr. James Kerr, medical superintendent of the Bradford School Board. The tests employed were designed to detect every child who had not good distant vision with one eye at least, the list of children thus obtained including those with defect of distant sight from all causes, remediable or otherwise. Such a list having been made, it was an easy matter to more fully examine all the children thus tabulated, and to classify and deal with them as might be necessary. In the report, tables are given showing the number of children examined, and the percentage of defective eyesight in the different standards from one to seven. A perusal of Dr. Kerr's report will, in the opinion of our contemporary, well repay those who have to conduct similar examinations of large numbers of school children.

WE have received from the Deutsche Seewarte (Hamburg) the report of its labours during the year 1894. The duties of this institution differ materially from those of the German Meteorological Institute (Berlin), whose report we lately noticed, inasmuch as the former deals specially with weather prediction and marine meteorology. In both of these branches great activity is shown, and we have frequently referred to the useful work carried on. The detailed discussion of the meteorology of the various oceans, for the benefit of seamen, the preparation of synoptic weather charts of the North Atlantic Ocean, for the advancement of practical meteorology, and the publication of observations taken in remote parts of the world, are noteworthy instances of the industry of the institution. For the purpose of obtaining information relating to maritime meteorology, it has not only established many agencies in German ports, but the Consuls in several foreign ports, including English, also take part in enlisting observers and supplying the necessary registers; the result being that about 450 voluntary observers were co-operating at the end of the year in the mercantile marine alone.

THE annual report of the Department of Mines and Agriculture, New South Wales, for the year 1894, has come to hand. In it reference is made to the resignation of the position of palæontologist of Mr. Robert Etheridge, occasioned by his accepting the curatorship of the Australian Museum. Mr. Etheridge will, however, we are pleased to notice, still retain connection with the department, having, the report says, volunteered to act as honorary consulting palæontologist.

WE have received from the Keeper of the Manchester Museum, Owens College, a new handy guide to the museum, which has been compiled for the purpose of indicating cursorily the principal objects in the building and its general arrangement, for the benefit of visitors whose time is limited. To those who can afford time to pay several visits, the illustrated guide is recommended as being more complete and useful.

THE new part of the *Asclepiad*, Sir B. Ward Richardson's quarterly, contains articles on "Cycling and Heart Disease," "The late prevailing Epidemic," and, with portrait, "John Abernethy, F.R.S."

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*, ♂ ♀) from India, presented by Mr. Hugh H. Collis; a White-tailed Sea-Eagle (*Haliætus albicilla*) from Northern Russia, presented by Mr. Robert Ashton; two Red-backed Shrikes (*Lanius collurio*), British, presented by Mr. C. Ingram; a Natterjack Toad (*Bufo calamita*) from Surrey, presented by Mr. Hanley Flower; a Melodious Jay Thrush (*Leucodioptron canorum*), deposited, a —— Capuchin (*Cebus ?* ♂), a Porto Rico Pigeon (*Columba corensis*), a Vinaceous Pigeon (*Columba vinacea*), a Barn Owl (*Strix flammea*), seven Adorned Ceratophrys (*Ceratophrys ornata*) from Brazil, purchased; a Great Kangaroo (*Macropus gigantus*, ♂), a Rufous Rat Kangaroo (*Hypsiprymnus rufescens*, ♂), a short-headed Phalanger (*Belideus breviceps*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE FORMS OF JUPITER'S SATELLITES.—A paper, by Mr. S. I. Bailey, on the forms of the discs of Jupiter's satellites, is communicated by Prof. E. C. Pickering to the current *Astrophysical Journal*. A number of observations of the satellites has been made with the thirteen-inch refractor at the Arequipa Observatory; and the results were: "Under the best conditions, that is, with the instrument in perfect adjustment and good seeing, satellites II., III. and IV. were always seen round. Satellite I. was twice seen having an apparent elongation in the same direction as Jupiter. In both cases the satellite was near the planet. On the second occasion, I., when off the disc, but near Jupiter, appeared elongated, but an hour later, plainly seen on the disc of Jupiter, it appeared perfectly round. On the other hand, the shadows of I. and III. on other nights were seen elongated. Several occultations and transits were observed, but the limb of Jupiter was not seen when, to me, it gave any indication of transparency. . . . During the hours given, we failed to detect any systematic change of form in any of the satellites. These observations, scattered through the cloudy season, may not be the best possible, for the same observers and instrument in Arequipa, nevertheless it does not seem probable to me that any frequent periodic recurrence of an ellipticity, approximating in amount that of Jupiter itself, would have escaped detection."

EPHEMERIS OF SWIFT'S COMET.—The following elements and ephemeris of Swift's comet, the reappearance of which was announced last week, have been computed by Dr. Berberich, and are published in *Edinburgh Circular*, No. 45. The elements are deduced from the observations: Mount Hamilton, August 21; Nice (M. Javelle), August 24; Hamburg, August 25.

Another observation of August 23, made by Mr. J. Witt at the Urania Observatory, Berlin, is closely represented by the ephemeris. Dr. Berberich thinks the comet will possibly belong to the group of periodic comets with short revolution.

The brightness at August 21·5 has been taken as unity.

COMETS AND THE SUN-SPOT PERIOD.—Since the discovery of the periodicity of the sun-spots, investigations have shown that many terrestrial phenomena are, and others may be, closely allied to it. These are generally looked upon as results due to the variation in the sun. If it were found that comets had an eleven yearly period, we should have the question before us as to whether this period be the result of this period, or whether the period depended to a certain extent on this periodical cometary influx. If the sun, as has been supposed, were fed, so to speak, with cometary matter, then the spot period would naturally be dependent on some external source of supply such as this. But since the solar atmosphere has a circulation which seems now to have been fairly shown to be the cause of this periodicity, such an outward supply of energy is not thought now to be of such importance as would have been the case some years ago. This does not take away the interest, however, from Herr J. Unterweger's investigation concerning the connection of spots and appearances of comets, but would rather instigate it. The author has, by a strict examination of the elements of the larger periodical comets, obtained a function which can be represented mathematically by a formula, and from which an eleven-yearly period since 1740 can be recognised. From the year 1833, also, the maxima and minima points fall together, without exception, with those of the sun-spot curves. In determining the length of the period, the amplitude of the period was set for each series as a function of the length of the period, and thus each value for the duration of the period ascertained. The calculation was so arranged that two neighbouring values, which made the amplitude a minimum, were also determined. The values for the function came out as 8·682, 11·220, 13·365 years, those for the series showing the relative number of sun-spots being 8·721, 11·254, 13·424 years.

To determine also whether the points of maxima and minima of the function were coincident with those for the series showing sun-spot numbers, the curves drawn from the values derived [illegible] to such an extent that a secondary maximum could be [illegible] of them in similar positions.

Other [illegible] which the investigator indicates as having been [illegible] identification of the thirty five yearly sun-spot period, the function giving larger values in 1778, 1816, 1848 and 1882, and smaller minima in 1764, 1806, 1834 and 1867; the time between two successive maxima being in the mean 34·8 years.

The [illegible] period 1764–1806, with maximum at 1777–80, [illegible] number of sun spots and a large [illegible] which began in 1768 and ended about 1785. The 1806–1834 interval, with a maximum at 1816, corresponds to a maximum of sun-spot and to an intense *glets herverstors* from 1814 to 1824. The third and fourth periods are also likewise explained.

Cases are also made out for the secular variations in the climate, and a suggestion is thrown out that if we may look upon "Kometen als stark elektrische Massen," then at the times of their maximum number and least distances from the earth, small induced currents may be set up, which will be recorded by the magnetic needle; this latter question has not, however, been investigated.

THE SUN'S PLACE IN NATURE.[1]

XI.

The Clock Rate.

THE proper regulation of this clock error and consequent "trail" of the spectrum across the plate parallel to itself are essential to the success of photographs taken by the objective prisms. The spectrum of a bright star must obviously be made to trail more quickly than that of a fainter one, and a shorter exposure is sufficient. Since for the same clock error, and in the same time, a star near the pole will give a shorter trail than one nearer the equator, declination must also be taken into account. Keeping a constant clock error, equal widths of spectrum for stars of different declinations may be obtained by lengthening the time of exposure for stars away from the equator, but in that case, the stars near the pole would be over-exposed in relation to those nearer the equator.

The exposure given to stars of equal magnitudes should evidently be the same, no matter in what part of the sky they may be situated, and the clock error should, therefore, be increased in proportion to the secant of the angle of declination.

The light-ratio of stars being $2·512^n$, where n expresses the difference in magnitude, the time of exposure must vary in the same proportion, and the clock error in inverse proportion. Thus, where 5 minutes' exposure is sufficient for a first-magnitude star, 31 minutes is required to obtain a fully-exposed spectrum of a star of the third magnitude. This law, however, only applies to photographic magnitudes, and must be modified according to the type of spectrum or the colour of the star.

The red stars, being much weaker in blue and violet rays than the yellow or white stars, require much longer exposures than white stars of equal magnitude. To obtain a spectrum of β Pegasi extending to the K line, for example, at least three times the exposure required by a white star of similar magnitude must be given.

For conveniently adjusting the exposures, tables have been constructed which show at a glance the position of the regulator for a star of given magnitude and declination.

It is obvious that with an instrument of high dispersion, the number of stars it is possible to photograph is very limited, as the long exposures required for the fainter stars are impracticable, and, even if possible, the definition of the lines would be destroyed by atmospheric tremors.

Hence, it is at present only possible to photograph the spectra of the faint stars on a very small scale. With an objective of 8 inches aperture and 44 inches focal length, and a prism of 13° refracting angle, Prof. Pickering has photographed the spectra of stars down to the eighth magnitude. These spectra are about 1 centimetre long, and a millimetre broad, and though they do not show a very great amount of detail, they are sufficient to reveal the type of spectrum.

With an instrument capable of photographing faint stars, a large number of spectra may be taken at one exposure; but, with the instruments of larger dispersion, this is not generally the case, as there are few bright stars of nearly equal magnitude sufficiently close together.

The Electrical Control.

In consequence of the great accuracy required in the driving of the telescope when long exposures are necessary, the 10-inch equatorial has been fitted with a simple and inexpensive form of electrical control. This is a modification of that designed by Mr. Russell, of the Sydney Observatory.[2] The existing driving

1 Revised from shorthand notes of a course of Lectures to Working Men at the Museum of Practical Geology during November and December, 1894. (Continued from page 4[illegible].)

2 *Monthly Notices* [illegible]

gear has been altered so that the driving rod performs its revolution in a second, and the motion is then communicated to the driving screw through a small worm wheel. The driving rod is vertical and in two parts, the lower portion ending in a faced ratchet wheel, 3 inches in diameter, and with 200 teeth. The upper part of the rod ends in an arm at right angles to itself, and this arm carries a ratchet of suitable shape held down by an adjustable spring. An electro-magnet connected with the controlling pendulum, is arranged so as to only permit the ratchet to pass it once a second (see Fig. 42). If the clock be driving too quickly, the ratchet is held until the stop is raised by the pendulum. When held in this way the ratchet is lifted out of the teeth, and the driving clock itself is not affected.

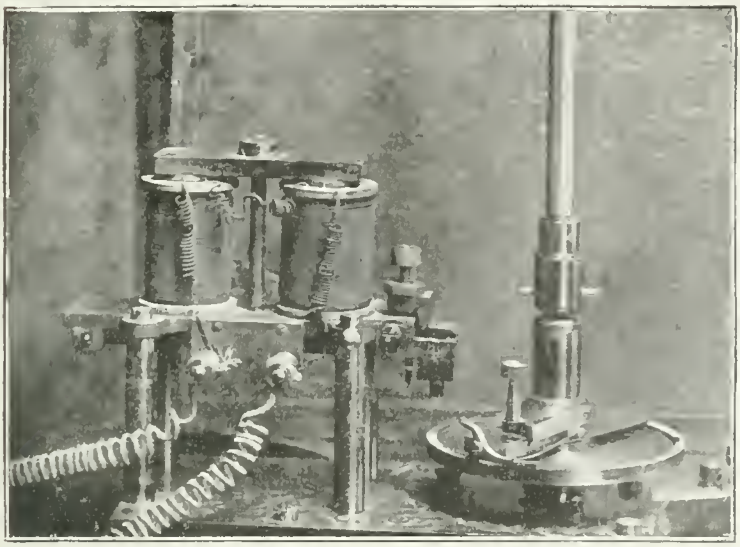

FIG. 42. Electrical control for 10-inch equatorial.

In order that this form of control may be effective, it is essential that the clock should be going too quickly, as it is only capable of retarding the driving-rod.

The controlling pendulum is, of course, regulated to the rate required for the particular star which is being photographed.

In Mr. Russell's form of control the two parts of the driving rod are connected by friction plates. It was found, however, on testing this arrangement, that when the upper portion was held by the electro-magnet the rate of the governors was seriously retarded; hence I introduced a ratchet wheel, and its working leaves nothing to be desired.

Enlargement of the Negatives.

Many of the negatives taken have been enlarged about nine times on glass, and further copies have been taken on bromide paper, bringing the enlargement up to about twenty-five times the size of the original.

Owing to various causes the photographic spectra obtained by the method of trails show irregularities resembling the lines along the spectrum observed when the slit of a spectroscope is partly clogged with dust. It has been noticed that the period of the irregularities is equal to the time of revolution of the main driving screw of the telescope, and hence they may be accounted for by supposing the driving gear to be mechanically imperfect. In that case some of the parallel lines which, by their juxtaposition form the broadened spectrum, are superposed, while others are drawn apart, thus giving rise to dark and bright lines parallel to the length of the spectrum. These lines are more apparent in the case of bright stars than fainter ones. If the telescope were driven with perfect regularity and the atmosphere were quite steady, we should obtain a spectrum of uniform intensity along its width. This condition has very nearly been obtained in some cases.

The irregularities above described are eliminated in the enlarged negatives by giving them a very slight up-and-down motion during exposure in a direction parallel to the lines of the spectrum. This was originally done by hand, but a negative holder has been constructed in which the necessary motion is given to the negative by a small driving clock.

A diagram of the arrangement is given below. The only drawback to this method is that defects of the film are apt to produce, by a succession of their images on the enlarging plate, lines (generally very faint) which have a semblance of the true spectrum lines.

To distinguish the real lines from the artificial ones, a direct enlargement of the spectrum is made on the same plate alongside the other, the to-and-fro motion being dispensed with. By a comparison of the two enlarged strips, one can see at a glance which are the true lines of the spectrum, and which are those produced by small irregularities on the film. It may be stated that Dr. Scheiner has also used a somewhat similar method to the one described, the only difference being that he caused the plate on which the enlargement was to be taken to have the oscillating motion, instead of the original negative. The method employed by me, though no account of it had been published, had been in use for some time before Dr. Scheiner's method was announced.[1]

My object was not so much to obtain photographs of the spectra of a large number of stars, as to study in detail the spectra of comparatively few; hence many of the stars have been photographed several times with special exposures and foci for different regions of the spectrum.

As in the case of stellar spectra observed by eye, the photographic spectra vary very considerably in passing from star to star.

In the classification of stars adopted from a consideration of the visual observations, only the broader differences in the spectra have been taken into account. Prof. Pickering, however, has suggested a provisional classification in connection with the Henry Draper Memorial photographs of stellar spectra, but this chiefly relates to photographs taken with small dispersion. Now that it has become possible to obtain large dispersion photographs of the spectra, much more detail is revealed, and hence I determined to deal with the presence, or absence, or changes of intensity, of individual lines to a greater extent than Prof. Pickering has done in his observations so far published.

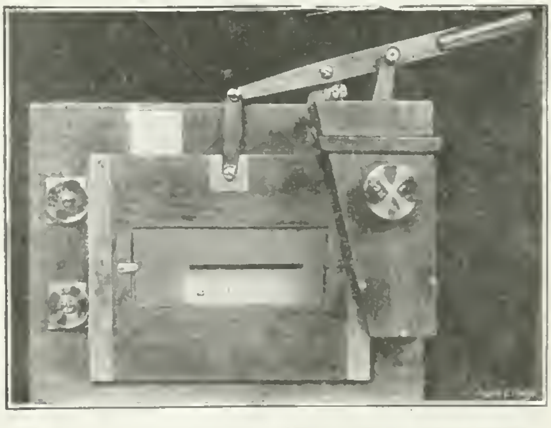

Fig. 43. Negative holder used in enlarging

In the first instance, I arranged the various stars of which the spectra have been photographed in tables, without reference to any of the existing classifications, and not taking into account the finer details.

The basis upon which this first grouping was founded is the extent of the continuous absorption at the blue end of the spectrum. Such a distinction was not possible in the case of

[1] NATURE, vol. xlii. p. [illegible]

eye observations, and it is only by photographs that a classification from this point of view can be made.

Some spectra show a remarkable continuous absorption either in the ultra-violet or violet, in others this absorption extends to about K, whilst in a third class it reaches as far as G.

These considerations gave four marked groups. Each of these main groups are next sub-divided into sub-groups by the most marked differences in the spectral lines. I do not propose to give the detailed inquiry in this place.

The important fact which stood out when the photographic attack had got so far was that, whether we take the varying thicknesses of the hydrogen lines or of the lines of other substances as the basis for the arrangement of the spectra, it was not possible to place all the stars in one line of temperature, but it was necessary to arrange the stars in two series.

When this sorting was completed, I was in a position to consider the various divisions of the photographic spectra thus arrived at, in relation to the groups which were previously suggested from a discussion of eye observations. It is clear that if I got the same results the first conclusions would be strengthened.

We have, therefore, to inquire how far this condition is satisfied by the mass of new facts at our disposal. This involves the consideration of some points in connection with the meteoritic hypothesis, and it must specially be borne in mind that the fundamental difference between mine and other classifications is that it demands the existence of bodies of increasing as well as bodies of decreasing temperatures.

Since in my classification the connection between nebulæ and stars is insisted on, it was necessary to obtain a spectrum of one of the brightest of the nebulæ as a term of comparison. The nebula of Orion was selected, and a photograph taken with a 30-inch silver on glass reflector in February 1890. This photograph contained 54 lines, which were carefully tabulated for the purposes of the comparison to which reference has been made.

The Complex Origin of the Spectra of Nebulæ.

On the hypothesis, the bright lines seen in the nebulæ should have three origins:

(1) The lines of those substances which occupy the greatest volume (or largest area in a section); in other words, the lines of those substances which are driven furthest out from the meteorites and occupy the interspaces, when possibly they may be rendered luminous by electricity. Chief among these, from laboratory experiments, we should expect hydrogen, and next, from the same experiments, we should expect gaseous compounds of carbon.

(2) We are justified in assuming that the most numerous collisions will be partial ones—grazes—sufficient only to produce comparatively slight rises in temperature. The nebula spectrum, so far as it is produced by this cause, will therefore depend upon the phenomena produced in greatest number, and we may hence expect to find the low temperature lines of various metallic substances.

(3) In addition to the large number of partial collisions there will be a relatively small number of end-on collisions, producing very high temperature,[1] and, so far as this cause is concerned, there will be some lines produced which are associated with very high temperatures.

Combining these conclusions, in the spectra of nebulæ we should expect to find evidence of

Hydrogen and compounds of carbon.
Low temperature metallic lines and flutings.
Lines which are only produced at very high temperatures.

The Passage to Bright-line Stars.

On the hypothesis, the lines seen in the spectra of bright-line stars should, in the main, resemble those which appear in nebulæ. They will differ, however, for two reasons:—

(1) Owing to partial condensation of the swarm the hydrogen area will be restricted, and the bright lines of hydrogen will lose their prominence; the volume occupied by the carbon compounds will be relatively increased, and the brightness of the carbon bands will be enhanced.

(2) On account of the increased number of collisions, more meteorites will be rendered incandescent, and the continuous spectrum will be brighter than in nebulæ.

[1] [illegible] *Proc.*, vol. liii, p. [illegible]

Stars of Increasing Temperature.

Initially, each pair of meteorites in collision may be regarded as a condensation.

Ultimately, when all the meteorites are volatilised, there will only be one condensation, in the shape of a spherical mass of vapour. Between these points there must be other conditions.

(Stage 1.) At the stage of condensation immediately following that of the bright-line stars, the bright lines from the interspaces will be masked by corresponding dark ones produced by the absorption of the same vapours surrounding the incandescent meteorites. One part of the swarm will give bright lines, another dark lines at the same wave-lengths, and these lines will therefore vanish from the spectrum. The interspaces will be restricted so that absorption phenomena will be in excess, and the first absorption will be that due to low-temperature vapours, that is, fluting absorptions of various metals. The radiation spectrum of the interspace will now be chiefly that of the compounds of carbon. Under these conditions we know from laboratory experiments[1] that the amount of continuous absorption at the blue end will be at a maximum.

(Stage 2.) With further condensation the radiation spectrum of the interspaces will gradually disappear, and the fluting absorptions will be replaced by dark lines, for the reason that the incandescent meteorites will be surrounded by vapours produced at a higher temperature, the number of violent collisions per unit time and volume being now greatly increased. This dark line spectrum need not necessarily resemble that of the Sun.

(Stage 3.) The line absorption and the continuous absorption at the blue end of the spectrum will diminish as the condensations are reduced in number, for the reason that only those vapours high up in the atmospheres surrounding the condensations will be competent to show absorption phenomena, in consequence of the bright continuous spectrum of the still disturbed lower levels of those atmospheres.

Among the more important lines which will disappear at this stage will be those of iron, for the reason that there will be bright lines from the interspaces occupying the same positions as the dark lines produced by the absorption of the vapour surrounding the stones.

The number of violent collisions per unit time and volume being further increased, we should expect the absorption of very high temperature vapours.

The Hottest Stars.

Ultimately, then, we should expect that the order of the absorbing layers will follow the original order of the extension of the vapours round the meteorites in the first condition of the swarm, and the lines seen bright in nebulæ, whatever their origins may be, should therefore appear almost alone as dark lines in the hotter stars, and the hydrogen especially should have its lines broadened with each increase of depth in the atmosphere. The continuous absorption at the violet end of the spectrum will be at a minimum. If, when the hydrogen lines are thick the swarm is not yet completely condensed, that is, if there be nebulous matter surrounding the central mass of vapour, a fine bright line will be seen down the centre of each dark one.

Stars of Decreasing Temperature.

When we consider the cooling condition, that is, what happens when the temperature of the mass of vapour is no longer increased by the fall towards the centre of meteorites composing the initial swarm, we should expect to find the phenomena indicated below.

(Stage 1.) The hydrogen lines will begin to thin out, on account of the diminishing depth of the absorbing atmosphere, and new lines will appear.

The new lines will not necessarily be the same as those observed in connection with the stars of increasing temperature.[2] In the latter there will be the perpetual explosions of the meteorites affecting the atmosphere, whereas in a cooling mass of vapour we have to deal with the absorption of the highest layers of vapours. Those lines which will first make their appearance, however, will be the longest low temperature lines of the various chemical elements.

[1] Lockyer and Roberts-Austen, *Roy. Soc. Proc.*, 1875, p. [illegible]
[2] *Roy. Soc. Proc.*, vol. xlv, p. [illegible]

(Stage 2.) The hydrogen lines will continue to thin out, and when the absorption of the hotter lower layers makes itself felt the spectra will show the high temperature spectra of the various chemical elements, showing many more lines. The difference between these and the lines seen in stars of increasing temperature should be one due to the different percentage composition of the absorbing layers, so far as the known lines are concerned.

With this increasing line absorption there will be a recurrence of the continuous absorption in the ultra-violet.

(Stage 3.) With the further thinning of the hydrogen lines and reduction of temperature of the atmosphere, the absorption flutings of the compounds of carbon should come in.

So much, then, for what we should expect, assuming the hypothesis to be true.

I now proceed to show how far these requirements are satisfied by the mass of new facts now at our disposal.

THE ACTUAL PHENOMENA RECORDED ON THE PHOTOGRAPHS.

Nebulæ.

The photographs of the spectrum of the Orion Nebula show lines at wave-lengths which approximate very closely to the lines of hydrogen, to flutings which appear in the spectra of compounds of carbon, to a fluting of magnesium at 5006, and to the longest flame lines of iron, calcium, and magnesium.

The chromospheric line designated D_3 has been recorded in the visual spectrum of the Orion Nebula by Dr. Copeland,[1] and the observation has since been confirmed by Mr. Taylor.[2]

The line which is always associated with D_3 in the spectrum of the chromosphere, viz. that at λ 4471 (Lorenzoni's *f*), is also shown in the photograph of the spectrum of the Orion Nebula.

The requirements of the hypothesis with regard to nebulæ are therefore met in every point so far considered by the new facts.

Dividing up the lines into the three groups of origins suggested, we have in the case of the Orion Nebula :—

(*a*) Spectrum of large interspace (= that of non-condensable gases driven out of the meteorites) = lines of hydrogen ; flutings of carbon.

(*b*) Spectrum of vapours produced by the large number of partial collisions = fluting of magnesium at λ 5006 ; low temperature lines of iron, calcium, and magnesium.[3]

(*c*) Spectrum of the vapours produced at a very high temperature by the relatively small number of end-on collisions. The solar chromosphere may be taken as indicating the spectrum associated with this very high temperature = chromospheric lines, $D_3 + \lambda\,4471$.[4]

Bright-Line Stars.

Prof. Pickering has shown that the Draper Memorial Photographs (copies of which he has very kindly forwarded me) prove that bright-line stars are intimately connected with the planetary nebulæ, the lines in the spectra being almost identical.

The main point of difference is that the chief nebular line near λ 5006 is not seen in the spectrum of bright-line stars, and this no doubt is due to the relative absence of feeble collisions as condensation goes on. The brightening of this line in the spectra of Nova Cygni and Nova Aurigæ, as the stars faded away, is sufficient evidence that it is associated with low temperature, and hence it is not surprising to find that it is absent from the spectra of the bright-line stars, which on this hypothesis are hotter than the nebulæ, since they are more condensed.

I have stated that we should expect the hydrogen lines to be fainter, and the carbon flutings, and the continuous spectrum to be brighter than in nebulæ.

(*a*) The hydrogen lines are decidedly less prominent. Indeed they were not recorded at all in the eye observations of γ Argûs (Arg.-Oeltz., 17681), of Wolf and Rayet's second and third stars in Cygnus,[1] but they are shown in Prof. Pickering's photographs.

(*b*) In my previous discussion of these bodies[2] I showed that there was evidence of a very considerable amount of carbon radiation in the visible region of the spectrum. Subsequent work and an examination of Prof. Pickering's photographs have strengthened this view.

(*c*) There can be no question as to the continuous spectrum being brighter in bright-line stars than in nebulæ.

Stars of Increasing Temperature.

(Stage 1.) We should expect the spectra to show—

(*a*) Absence of bright lines.

(*b*) The presence of dark metallic flutings.

(*c*) The presence of bright carbon flutings.

(*d*) Continuous absorption in the violet.

Many of the stellar photographs answer these requirements.

(*a*) They show no bright lines under normal conditions, but if the stars are variable, the disturbances which bring about the change of luminosity at maximum, produce bright lines in the spectrum as in the case of the spectrum of Mira Ceti photographed by Prof. Pickering.

(*b*) Dark flutings have been photographed in several spectra.

(*c*) The photographs appear to show the actual presence of carbon radiation ; further photographs are being obtained to carry on the inquiry.[3]

The stars of this class which have already been photographed at Kensington are well advanced in condensation, as indicated by the numerous dark lines, and all the flutings, both bright and dark, are confined to the region less refrangible than G. We should therefore not expect to get the more refrangible carbon flutings. It is among the least condensed stars that we should expect the bright carbon to be more manifest, and, indeed, in the spectrum of Mira Ceti photographed by Prof. Pickering, there is strong evidence of the presence of one of the more refrangible carbon bands commencing at λ 4215.

(*d*) The photographs fully demonstrate that there is a very considerable amount of continuous absorption in the ultra-violet or violet.

It must be added that the sequence of the spectra photographed resembles that deduced from eye observations, and the wonderful thing is that the observations of Dunér will bear the severe test which has thus been applied to them.

(Stage 2.) At this stage we should expect—

(*a*) Diminution in the amount of continuous absorption.

(*b*) Spectrum consisting of dark metallic lines, but possibly differing from the solar spectrum.

These conditions are fulfilled by the stars of which α Tauri and γ Cygni may be taken as types. The continuous absorption is least in the latter. These spectra show numerous metallic lines, but they do not exactly resemble the solar spectrum. The hydrogen lines are comparatively thin, while other lines have very different intensities as compared with lines in the solar spectrum.

In these stars we have to deal with the varying volatilities of the meteoretic constituents of the swarm, while in the case of stars which are cooling we have to deal with successive combinations rendered possible by the fall of temperature in a gaseous mass. Hence differences in the spectra are to be expected.

(Stage 3.) The phenomena which would be expected on the hypothesis, at this stage, are fully satisfied by such stars as α Cygni, β Orionis, ζ Orionis, ϵ Persei. In these stars there is

[1] *Monthly Notices*, vol. xlviii., p. 360.

[2] *Ibid.*, vol. xlix. p. 124.

[3] I have previously given evidence deduced from eye observations, indicating the presence of other low temperature flutings of manganese and magnesium.

[4] Since the lectures were delivered (and in this I summarised a paper I had previously sent in to the Royal Society), this part of the hypothesis has been enormously strengthened by the discovery of a new series of gases which the spectrum indicates are associated with the one giving the line D_3 which I discovered in 1868 and named helium. These new gases contain many lines in addition to D_3 and 4471, which appear both in the solar chromosphere and nebula of Orion and stars of increasing temperature.

[1] *Roy. Soc. Proc.* vol. xliv., pp. 33-43.

[2] *Ibid.*

[3] Subsequent eye observations by myself and Mr. Fowler seemed to leave no doubt as to the presence of these bright carbon flutings (*Roy. Soc. Proc.*, vol. xlvii. p. 40). Dr. Copeland had previously made important observations of "Nova" Orionis with reference to this point (*Monthly Notices*, vol. xlvi. p. 112), and he identified one of the bright bands as "the great hydrocarbon band seen in the spectrum of every comet that has been examined under favourable circumstances." Referring to his observations of α Orionis, Mr. Maunder ("Greenwich Spect. Observations," 1889, p. 22) states that "the carbon band at 5164 was coincident (within the limits of observation with this dispersion) with the bright space towards the blue of Dunér's band 7."

[illegible] the violet or ultra-violet, and the [illegible] is [illegible] absorption, the iron lines quite [illegible] after such a star as α Cygni is passed. The new lines which now make their appearance include the chromospheric line at λ 4471, and possibly a few others. It is important to note that the photographic region of the spectrum of the chromosphere has not yet been fully investigated, and hence a fair comparison with the spectra of these stars in the region F to K is not yet possible. M. Deslandres and Prof. Hale have photographed the chromospheric spectrum in the region more refrangible than H, but have not as yet published any account of the spectrum in the region now under discussion.

The Hottest Stars.

The conditions required by the hypothesis with regard to the stars at this stage are satisfied by such stars as ζ Cassiopeiæ and α Andromedæ.

In these stars we have—

(a) Broad lines of hydrogen, and

(b) Other absorption lines, chiefly of unknown origins, agreeing in position with some of the bright lines which appear in nebulæ.

It will be seen, then, that these considerations of the conditions of increasing temperature demanded by the hypothesis, have enabled us to determine that a long series of stellar spectra is in all probability a series in *ascending* order of temperature. All the phenomena we should expect, on the hypothesis, are met with among the photographs.

We have next to consider the phenomena connected with stars of decreasing temperature.

Stars of Decreasing Temperature.

(Stage 1.) With the failure of the supply of meteorites falling on the now condensed mass, cooling will commence, and the longest lines in the spectra of the various chemical elements should make their appearance. This condition is met with and is well evidenced by the iron lines in the spectrum of Sirius.

(Stage 2.) The conditions at this stage of cooling are satisfied by δ Cassiopeiæ, β Cassiopeiæ, α Canis Minoris. In these stars we get, in addition to fairly broad lines of hydrogen, nearly all the lines which appear in the solar spectrum, and these, it is well known, agree in the main with the arc spectra of the various chemical elements.

(Stage 3.) Such stars as Capella and Arcturus represent the conditions which are required by the hypothesis at this stage of cooling. The metallic line absorption is again at a maximum, and we find the lines of the various chemical elements similar to those seen in Stage 2 of the ascending series, but with different intensities and with different amounts of continuous absorption at the violet end of the spectrum. This difference, so far as the known lines are concerned, will be due to a different percentage composition of the absorbing mass of vapour.

Continuous absorption in the violet commences at this stage. There is [illegible] evidence of carbon in the solar spectrum, and in the spectrum of Arcturus—the only star which has yet been investigated with special reference to this point.

Hence, it seems probable that "the indications of carbon will go on increasing in intensity slowly, until a stage is reached, when, owing to the reduction of temperature of the most effective absorbing layer, the chief absorption will be that of carbon."

It is evident that all such stars will be dim, and hence their spectra have not been dealt with in this preliminary survey of the photographic spectra of the brighter stars.

General Results of the Discussion.

The general result of the above discussion so far as it goes is as follows:—Among the 171 stars already considered there are mainly two series of spectra, one representing the [illegible] of increasing temperature, while the other represents the series of decreasing temperature. The fundamental requirement of the meteoritic hypothesis is, therefore, fully justified by the discussion of the photographs.

A very interesting point in connection with the two series [illegible] the one spectrum, such as that of α Andromedæ [illegible] characteristics common to both, and we may [illegible] connect the two series together by this spectrum. In this case we should find, if we commence with the first spectrum in Series 1, say that of α Herculis, that the continuous absorption diminishes and that the breadth of the hydrogen lines regularly increases, until such a spectrum as that of α Andromedæ is reached. Then the condition would be reversed, the breadth of the hydrogen lines diminishing and the continuous absorption in the ultra-violet increasing in extent until such a star as Arcturus is reached.

It may be stated finally that the sequence now determined from the photographs follows exactly the same order as the groups originally suggested by the hypothesis, from a discussion of the eye observations. That is, it is not necessary to interchange any of the groups in order to obtain agreement with the photographic results.

J. NORMAN LOCKYER.

SCIENCE IN THE MAGAZINES.

PROFS. WEISMANN, Haeckel, and Karl Pearson will probably have something to say in reply to a paper which Dr. St. George Mivart contributes to the *Fortnightly*. The paper deals with what is described as "Denominational Science," in which dogma takes the place of facts, and persuasions are given out as if they were demonstrated truths. Dr. Weismann comes under Dr. St. George Mivart's displeasure in this regard; and a noteworthy characteristic of his is said to be "the confidence with which he propounds hypotheses which are either purely imaginary, or are only supported by an infinitesimal basis of fact, and the readiness with which he comes forward with a fresh gratuitous hypothesis, to replace others which have been refuted by newly-discovered truths." Prof. Haeckel is taken to task for the opinions expressed in his book on "Monism," lately translated into English. The bearing of Dr. St. George Mivart towards the book is indicated by the remark which opens the attack upon some of the points in it. We read: "It is difficult to say whether this small volume is more remarkable for the self-conceit and empty dogmatism, or for the ignorance it displays—ignorance concerning the most fundamental questions of which its treats." To assess these remarks at their proper value, it is necessary to read the article containing them, and the work to which they refer. Prof. Karl Pearson completes the trio upon whose views Dr. St. George Mivart outpours the vials of his wrath. His "Grammar of Science," and his remarks, in the *Fortnightly*, on Lord Salisbury's Oxford address, are given as evidence that "we have in England a denominational writer only second in self-confident dogmatism to Haeckel." All the members of the trio are held up as awful examples of "an unconscious slavery of the intellect to the mere faculty of the imagination, and the consequent presentation of shallow and illogical imaginary phantasms as deep and far-reaching intellectual truths in the form of baseless dogmas of denominational science." Huxley and Karl Vogt are compared by Prof. Haeckel in the *Fortnightly*, the former being given a higher place than the latter, both as regards his philosophical reasonings, and because he showed a much deeper insight into the essence and import of scientific things. Two pages of the six, which form Prof. Haeckel's notice, are taken up with a denunciation of Prof. Virchow's antagonism to Darwinism, and the theory of descent, especially with reference to the most important deduction from the theory—the descent of man from the ape. Virchow's dissent in this matter is used as one of the sticks with which Mr. F. H. Hill belabours agnosticism, and Huxley's support of it, in the *National*, under the title, "Gaps in Agnostic Evolution."

Mr. Herbert Spencer continues his analysis of "Professional Institutions," in the *Contemporary*, the evolution of the biographer, historian, and man of letters being traced this month. "The primitive orator, poet, and musician," says Mr. Spencer, "was at the same time the primitive biographer, historian, and man of letters. The hero's deeds constituted the common subject matter; and taking this or that form, the celebration of them became, now the oration, now the song, now the recited poem, now that personal history which constitutes a biography, now that larger history which associates the doings of one with the doings of many, and now that variously-developed comment on men's doings, and the course of things which constitute literature." Thus arose the rudiments of biography, history, and literature; and many facts illustrative of this early development are cited. Fiction developed out of biography and history, and gradually a class of story-tellers became differentiated. Indeed, for a time after fiction comes into existence, it is still classed and believed as biography. In our own times, we find

writers of history and biography and literature dividing into various classes, and finally there is the tendency of men of letters to unite into corporate bodies an integration which has only become possible in recent years. In the same magazine, under the title "Heredity Once More," Dr. Weismann replies at length to an article contributed by Mr. Spencer to the magazine last October.

Mrs. Percy Frankland writes popularly on "Sunshine and Life," in *Longman's Magazine*, which also contains an account, by Mrs. A. Lang, of the Rev. John Mulso and his unpublished letters to Gilbert White, of Selborne, whose *alter ego* he was. Miss A. Lorrain Smith describes "Ants as Mushroom Growers" in an illustrated article in *Good Words*: her paper deals with the leaf-cutting and fungus-growing ants of Nicaragua. The *Sunday Magazine* has a second paper by "Eha," on Indian jungle life. *Knowledge* contains an account of Prof. Petrie's conclusions with regard to a "Newly-found Race in Egypt"; and papers on "Wind-Fertilised Flowers," by the Rev. A. S. Wilson; "Satellite Evolution," by Miss A. M. Clerke; "Photographs of Elliptical and Spiral Nebulæ" (with a plate), by Dr. J. Roberts; and "Blind Cave-Animals," by Mr. R. Lydekker. *Chambers's Journal* contains short popular articles on "Cordite and its Manufacture," and "The Prospects of our Descendants in regard to Stature," and a gossip on the Great Auk.

We have received, in addition to the periodicals named in the foregoing, *Scribner's Magazine*, and the *Humanitarian*.

ON THE ELECTROLYSIS OF GASES.[1]

IN the experiments described in this paper I have used the spectroscope to detect the decomposition of gases by the electric discharge and the movement of the ions in opposite directions along the discharge-tube.

The method consists in sending the electric discharge through a tube so arranged that the spectra close to the positive and negative electrodes can easily be compared, the presence or absence of certain ions at these electrodes can thus be ascertained. This method is capable of much wider application than the one I previously used in my experiments on the "Electrolysis of Steam" (*Proc. Roy. Soc.*, vol. lii. p. 90), the use of which is attended with very great difficulty for any substance other than steam. The earlier method has, however, the advantage of being a quantitative method—the present one is only qualitative.

In my former experiment with steam, when I worked at atmospheric pressure and varied the length of the spark, I found that when the spark-length exceeded a certain length, d_1, there was an excess of hydrogen at the negative electrode and of oxygen at the positive, equal in amount to the quantities of hydrogen and oxygen liberated from a water voltameter placed in series with the steam-tube. When the sparks were shorter than a certain length, d_2, the hydrogen appeared at the *positive*, the oxygen at the *negative* electrode, but the quantity of these gases was again equal to the quantities liberated in a water voltameter placed in series with the steam-tube.

When the spark-length was between d_1 and d_2 the effects were irregular, and there seemed to be no connection between the amounts of gases liberated in the steam-tubes and those liberated in the voltameter.

In the following experiments in which the sparks were of constant length and the pressure was altered, corresponding effects were observed. Within certain limits of pressure definite and perfectly regular evidence of the separation of the ions of the gas sparked through was obtained; and the electrode at which a given ion appeared could be reversed by altering the pressure; there was, however, a range of pressures in which the separation of the ions was either not well marked or was irregular in character.

I shall begin by describing a very simple method of showing the separation of the ions produced by the discharge of electricity through a compound gas such as hydrochloric acid gas, which is applicable when the discharges through the constituent gases of the compound are of distinct and different colours; this is eminently the case with the hydrochloric acid gas, as the discharge through hydrogen in a capillary tube is red, through chlorine green.

Take a capillary tube of very fine bore, the finer the better (the tube I used was thermometer tubing of the finest bore I could procure), and insert platinum wires for electrodes in two small bulbs blown on the ends of the tube; then fill the tube with HCl gas, allowing it to run through the tube for a considerable time so as to get rid of any extraneous gas, and exhaust the tube so that the gas in it is at a very low pressure. Then when the discharge from a large induction coil passes through the tube, the following phenomena are observed. When first the discharge passes through the tube the colour is uniform throughout and of a greenish-grey; after the discharge has been passing for a little time the end of the tube next the cathode gets distinctly red, whilst that next the anode gets green; this difference in the colour at the ends of the tube goes on increasing until the tube presents a most striking appearance, the part near the cathode being bright red, while that near the anode is a bright green. The difference in colour attains a maximum value, and if the discharge is allowed to run for several hours the contrast between the two ends disappears to a very great extent; the discharge throughout the whole of the tube being pinkish and apparently passing mainly through hydrogen. This is doubtless due to the diffusion through the tube of the hydrogen which in the earlier stages of the discharge had accumulated about the cathode; one advantage of using very narrow tubes is that with them this diffusion is slow. When the tube is in this condition the colour of the discharge sometimes changes suddenly, and for a second or two is green instead of pink, showing that though in the main the discharge passes through hydrogen, it occasionally leaves the hydrogen and passes through the chlorine. This transference of the discharge from one constituent to another of a mixture of gases is not infrequently observed when the gases are mixed in certain proportions.

Some of these capillary tubes showed after the discharge had been passing through them for some time a peculiar patchy appearance, some portions of the tube being a much brighter red than the others, while other portions were green. In some tubes this occurred to such an extent that the discharge showed an irregularly striated appearance. This effect is due, I believe, to gases or moisture condensed on the walls of the capillary tube, and in some cases to irregularities in the chemical composition of the glass. I found that it did not occur if the tube before being used was heated for some time along its whole length to as high a temperature as it would stand without collapsing; this heating would tend to cleanse the walls of the tube. That differences in the quality of the gas also conspire to produce these patches is shown, I think, by the following phenomenon. A capillary tube of fine bore containing mercury vapour and a little water vapour developed a well-marked red patch; the tube was then heated for some inches in the neighbourhood of the patch. In general heating the tube makes the discharge yellow from the sodium vapour given off from the glass; in this case, however, the whole of the heated portion, with the exception of the patch, turned yellow; the patch itself withstood the heating and continued to show the bright colour characteristic of hydrogen.

Electrolytic Transport of one Gas through another. A tube of the shape shown in Fig. 1 was made of the finest bore thermometer-tubing; the extremities, C and D, of the tube in which

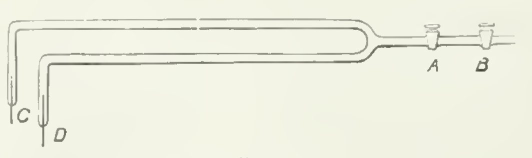

FIG. 1.

the electrodes were fused were bent down so as to be parallel to each other, and so near together that a slight motion of the tube suffices to bring either of the extremities in front of the slit of the spectroscope. The tube was mounted on a board moved by a lever; by moving this the observer at the spectroscope could readily bring the spectrum of either the positive or negative electrode into the field of view. A side tube, A B, was fused to the middle of the main tube and was provided with two taps; in the space between these taps a small quantity of any gas which it was desired to introduce into the main tube could be imprisoned, and could, by opening the tap A, be introduced into the discharge tube. The experiment consists in filling the main tube with a gas at a low pressure, observing the spectra at the

[1] Paper read at the Royal Society, by J. J. Thomson, M.A., F.R.S., Cavendish Professor of Experimental Physics, Cambridge.

two electrodes, then introducing by the side tube a very small quantity of gas into the main tube, and again observing the spectra at the two electrodes.

A tube was filled with hydrogen and showed no trace of the chlorine spectra; a very small quantity of chlorine was then let in through the side tube (in performing this experiment it is necessary to be careful that only a very small quantity of chlorine is introduced). After the discharge had been running through the tube for a short time, the chlorine spectrum was found to be bright at the positive electrode, though no trace of it could be detected at the negative. When the discharge was kept on for some time, the chlorine spectrum, though still visible at the positive electrode, got fainter; it did not appear at all at the negative. If a considerable quantity of chlorine was introduced through the side tube, the chlorine spectrum was visible at both electrodes, though it was brighter at the positive than at the negative.

When the induction coil was reversed, so that what was before the positive electrode became the negative, the first effect observed was that the chlorine spectrum flashed out with great brilliancy at the old positive electrode, and was much brighter than at any previous period. This, however, only lasted for a second or two; the chlorine spectrum rapidly faded away and for a time was not visible at either electrode. Soon, however, the chlorine spectrum appeared at the new positive electrode, having thus been transferred from one end of the tube to the other.

On again reversing the coil the same phenomenon was repeated. There is apparently no limit to the number of times this effect may be obtained; at any rate, I have driven the chlorine from one end of a tube to the other 14 times in succession by reversing the coil. The chlorine is always driven to the positive electrode, showing that the chlorine ion carries a charge of negative electricity. The same effect was obtained when a little vapour of bromine was introduced into the tube instead of chlorine. When, however, the capillary tube was filled with chlorine instead of hydrogen, and a little vapour of bromine let into the tube, the bromine went to the *negative electrode* instead of to the positive, as it did when introduced into the hydrogen tube. These experiments suggest that the two gases in the tube combine, and that the compound gas so formed is split up into ions which travel along the tube; that bromine when in combination with hydrogen is the negative ion, and therefore travels to the positive electrode; when, however, it is in combination with chlorine the bromine is the positive ion and travels to the negative electrode.

Another experiment tried was to let a little vapour of sodium into the middle of a capillary tube filled with air at a low pressure. To prevent the sodium vapour condensing on the walls of the tube, the whole tube was placed on a sand bath and the temperature raised so high that no condensation took place. After the discharge had run through the tube for about two hours the sand was removed from the tube, and the movement of the sodium vapour to the *negative* electrode was very apparent even without using a spectroscope, as there was a great patch of yellow light near the negative electrode and none in any other part of the tube.

Another experiment was to introduce a small quantity of hydrogen into a tube filled with air at a low pressure: the hydrogen made its way to the *negative* electrode. This experiment is a somewhat troublesome one, as it is exceedingly difficult to get these very fine capillary tubes so dry that the spectrum of the discharge does not show the hydrogen lines even before the hydrogen is introduced into the middle of the tube; indeed, I never succeeded in getting rid of the hydrogen lines at the very lowest pressures. By heating the tube and allowing dry air to pass through it for a long time, however, I got the tube so dry that it did not show the hydrogen lines at a pressure quite low enough to allow the discharge to pass freely through it. When the tube was in this state and hydrogen was let into the middle of the tube, the hydrogen spectrum appeared at the negative electrode, but not at the positive.

The appearance of hydrogen at the negative electrode when mixtures of [illegible] with other gases has been described by Mr. Baly in a very interesting paper in the *Philosophical Magazine*, [illegible] p. 200.

The preceding experiments suggest, I think, that this separation of two gases, A and B, by the discharge is due to the decomposition by the discharge of a chemical compound formed of A and B, in which the A atoms have a charge of electricity of one sign, the B atoms a charge of electricity of the opposite sign; these charged atoms under the influence of the electromotive force in the tube travel in opposite directions. Further, it follows from the experiment with the bromine vapour in an atmosphere of chlorine that the sign of the electrical charge on an atom of the same substance is not invariable, but depends on the substance with which this atom is in combination. We shall find numerous other instances of this change in the sign of the charge on an atom in experiments described in a later part of this paper.

Polarisation of the Electrodes.—This in the electrolysis of liquids is due to the accumulation at the electrodes of ions which have ceased to act as carriers of electricity. We have, I think, distinct evidence of a similar accumulation in the electrolysis of gases. For, as has been already described, after the discharge has been running for some time in one direction, giving the spectrum of some gas at one of the terminals, the spectrum of the gas at that terminal is momentarily brightened to a very great extent by suddenly reversing the direction of the discharge. After the current has been flowing for some time in one direction through, say, Cl in an atmosphere of H, the spectrum of the chlorine, though still visible at the positive electrode, gets faint, the chlorine apparently to a great extent ceasing to carry the discharge; when, however, the current is reversed, the atoms of chlorine can move freely, as they are not obstructed by the electrode, so that immediately after the reversal of the current there is probably more of the discharge carried by the chlorine than at any other time, and the chlorine spectrum is consequently brightest.

Discharge through a Compound Gas.—The separation of the ions by the discharge can be readily observed in a tube of the kind shown in Fig. 2.

It differs from an ordinary discharge tube merely in having a flat metal plate, A B, fastened across the tube. When the discharge passes through the tube, one side of the plate acts as a

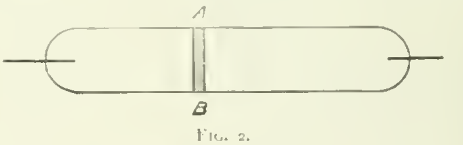

FIG. 2.

positive, the other as a negative, electrode. The tube is mounted on a stand, which the observer at the spectroscope can move by means of a lever so as to bring one side or other of the plate opposite the slit of the spectroscope; a very slight movement of the lever is sufficient to do this, so that the spectra at the two sides of the plate can readily be compared. I found that the results were more satisfactory when the current was kept flowing through the tube in one direction and the tube moved so as to bring the spectra at the two electrodes into the field of view than when the tube was kept fixed in one position and the current reversed. The latter method, however, suffices to show the separation of the ions in many cases, and it has the advantage of not requiring a plate across the tube; all that is necessary is to use for one of the terminals a disc whose plane is parallel to the slit of the spectroscope.

If the plate A B is thin, it is necessary to fuse it into the glass tube all the way round; otherwise, when the pressure is low, the discharge, instead of crossing the plate, goes through any little crevices there may be between the plate and the tube. The easiest way of making the tube is to use a plate about 0·5 cm. thick, cut from an aluminium cylinder which tightly fits the tube; with a plate of this thickness the narrow spaces between the tube and the plate are so long that the discharge goes through the plate rather than through the crevices.

The tube was filled with the gas to be observed and the spectra at the two sides of the plate compared. These spectra were in many cases found to differ in a very remarkable way; it was, however, only in exceptional cases that a line which was bright at one side of the plate was absolutely invisible on the other. The method used was to take two sets of lines, say A and B, as close together in the spectrum as possible, and compare the brightness of these sets of lines on the two sides of the plate; if it was found that the A lines were brighter on the positive side of the plate than on the negative, while on the other hand the B lines were brighter on the negative side of the plate than on the positive, then it was inferred that electrolytic

separation had occurred, and that the substance giving the A lines was in excess on the positive side of the plate, that giving the B lines on the negative. It is not safe to draw any conclusions from the variations in intensity of one line or one group of lines on the two sides of the plate, as the total quantity of light coming from the neighbourhood of the cathode often differs considerably from that coming from the anode. When, however, we get an increase in the brilliancy of one set of lines accompanied by a diminution in the brightness of another set, when we move across the plate we eliminate this source of error. The differences in the spectra at the two sides of the plate are most easily observed at pressures where there is not any very great difference between the luminosity of the cathode and the anode. As was mentioned at the beginning of the paper, there is a range of pressure within which the effects are irregular, and no decided differences are observed between the spectra at the two sides of the plate. It is desirable in these experiments to keep the tube on to the pipe as long as the experiment lasts, for the discharge always decomposes the compound gas, and unless the products of decomposition are continually pumped off and replaced by fresh supplies of the compound gas, the spectra of the discharge keep changing. With organic compounds this is especially necessary, as the character of the spectrum often changes entirely very shortly after the commencement of the discharge unless fresh gas is continually introduced.

In the following experiments the current was produced by a large induction coil with a mercury slow break.

When the tube was filled with hydrochloric acid gas at a low pressure, the separation of the hydrogen and chlorine was seen very distinctly, the hydrogen line being much brighter on the side of the plate which acted as the cathode (which we shall call the negative side of the plate) than on the positive side, while the chlorine, on the other hand, was brighter on the positive than on the negative side of the plate.

When the tube was filled with ammonia gas, the hydrogen lines were bright on the negative side of the plate, but were absent from the positive side, while on the positive side of the plate there was the positive pole spectrum of nitrogen, and on the negative side of the plate the negative pole spectrum of nitrogen and the hydrogen spectrum.

Sulphur Monochloride.—When the tube was filled with the vapour of this substance at a low pressure, the chlorine lines were brighter on the *negative* side of the plate than at the positive, while the sulphur lines were brighter at the positive side than at the negative. Thus the chlorine in this substance behaves in the opposite way to the chlorine in HCl; in the latter compound the chlorine iron has a charge of negative electricity, while in the sulphur monochloride it has a charge of positive electricity.

Influence of the Chemical Constitution of a Compound on the Sign of the Charge of Electricity on one of its Constituent Atoms.—In many organic compounds an atom of the electro-positive element hydrogen can be replaced by an atom of the electro-negative element chlorine without altering the type of the compound. Thus, for example, we can replace the four hydrogen atoms in CH_4 by chlorine atoms, getting successively the compound CH_3Cl, CH_2Cl_2, $CHCl_3$, and CCl_4. It seemed of interest to investigate what was the sign of the change of electricity on the chlorine atom in these compounds. The point is of some historical interest, as the possibility of substituting an electro-negative element in a compound for an electro-positive one was one of the chief objections assigned against the electro-chemical theory of Berzelius.

When the vapour of chloroform, $CHCl_3$, was placed in the tube, it was found that both the hydrogen and the chlorine lines were bright on the negative side of the plate, while they were absent from the positive side, and that any increase in the brightness of the hydrogen lines was accompanied by an increase in the brightness of those due to chlorine. The spectrum on the positive side of the plate was that called the carbonic oxide spectrum; when first the discharge passed through the tube, the spectrum on the positive side was the so-called candle spectrum, but this very rapidly changed to the carbonic oxide spectrum. The appearance of the hydrogen and chlorine spectra at the same side of the plate was also observed in methylene chloride and in ethylene chloride. Even when all the hydrogen in CH_4 was replaced by chlorine, as in carbon tetrachloride, CCl_4, the chlorine spectra still clung to the *negative* side of the plate. To test the point still further, I tried the analogous compound silicon tetrachloride, inserting a small jar in the circuit to brighten the spectrum. The chlorine spectrum was again brightest at the *negative* side of the plate, while the silicon spectrum was brightest at the positive. This is a very favourable case for the application of this method, as there are two silicon lines (wave-lengths 5058, 5043) quite close to two chlorine ones (wave-lengths 5102, 5078), so that their relative brightness can easily be compared. The experiment with the silicon tetrachloride is more conclusive than those with the carbon compounds, as with the latter the spectrum on the positive side of the plate is a band spectrum, and since the potential gradient when the discharge is passing is very much steeper on the negative side of the plate than on the positive, the effects observed might be supposed to be due to the circumstances on the negative side being better adapted for the production of line spectra than those on the positive. This explanation is not, however, applicable to the case of silicon tetrachloride, where the spectra on both sides of the plate are line spectra.

From these experiments it would appear that the chlorine atoms in the chlorine derivatives of methane are charged with electricity of the same sign as the hydrogen atoms they displace.

When we can determine the signs of the electrical charges carried by the atoms in a molecule of a compound, we can ascertain whether any given chemical reaction does or does not imply interchange between the electric charges on the atoms taking part in the reaction. Thus take the reaction

$$CH_4 + Cl_2 = CH_3Cl + HCl.$$

If we represent the sign of the charge of electricity carried by an atom by + or − placed below the symbol representing that atom, we may write the last reaction as

$$\underset{-\,+}{CH_4} + \underset{+\,-}{ClCl} = \underset{-\,+\,+}{CH_3Cl} + \underset{+\,-}{HCl},$$

so that this reaction could be produced by a rearrangement of the atoms without any alterations of their electrical charges.

If, however, we take the reaction—

$$\underset{+\,-}{HH} + \underset{+\,-}{ClCl} = 2\underset{+\,-}{HCl},$$

we see that in addition to a rearrangement of the atoms there must in this case be an interchange of electric charges between the atoms; for before combination half the hydrogen atoms had a negative charge, and half the chlorine atoms a positive one, whereas after combination no hydrogen atom has a negative charge, and no chlorine atom a positive one. We may thus distinguish between two classes of chemical reactions, (1) those which do not necessarily require any interchange of the electrical charges carried by the atom, and (2) those which do. It might, perhaps, repay investigation to see whether the occurrence of chemical change is affected by the presence of a third substance in the same way in these classes of chemical combination.

Another point to be considered is the effect of this difference between the chemical actions on the amount of heat developed during chemical combination. When hydrogen and chlorine combine the heat produced may be regarded as the joint effect of three processes:—

(1) The splitting up of the molecules $(\underset{+\,-}{H\ H})$ and $(\underset{+\,-}{Cl\ Cl})$ into the atoms $\underset{+}{H}$, $\underset{-}{H}$, $\underset{+}{Cl}$, $\underset{-}{Cl}$.

(2) A transference of electricity by which the negative charge on one atom of hydrogen is replaced by an equal positive charge, while the positive charge on an atom of chlorine is replaced by an equal negative charge.

(3) The combination of the positively electrified hydrogen atoms with the negatively electrified chlorine ones to form hydrochloric acid.

In that class of chemical action where the atoms retain their charge (2) is absent, so that if the change in energy occurring in the process (2) were considerable compared with the changes occurring in processes (1) and (3), the thermal effects of the two types of chemical combination ought to differ considerably. If the changes in energy occurring in the process (2) had a great preponderance over those occurring in (1) and (3), the thermal effects produced by the combination of two elements ought to follow very simple laws. For if 2 {H} is the excess of the energy of an atom of hydrogen charged with the negative electron over the energy of the atom charged with the positive electron, 2 {Cl} the excess of the energy of an atom of chlorine charged with the positive electron over the energy of the atom charged with the negative electron, then if we could neglect the energy changes in (1) and (3) compared with those in (2), the

mechanical equivalent of the heat developed when a molecule of hydrogen combines with one of chlorine to form two molecules of hydrochloric acid would be equal to 2{H} + 2{Cl}. Thus we see that if the energy changes in (2) preponderated largely over those in (1) and (3), the heat produced when an element A combined with another element B to form the compound AB, could be expressed as the sum of two numbers {A}, and {B}, where {A} depends solely on the element A, {B} solely on the element B. In some cases of chemical combination between dilute solutions there seems evidence that the heat produced can be expressed in this way (see Lothar Meyer, "The Evolution of the Doctrine of Affinity," *Phil. Mag.*, vol. xxiii. p. 504), but when we attempt to apply the same law to combination between gases, it seems utterly to break down; indicating that in such cases the greater part of the changes in energy occur in the splitting up of one set of molecules and the subsequent formation of others. This view seems to be supported by the phenomena attending the discharge of electricity through rarefied gases, for the smallest difference of potential which can send a discharge through an electrified gas (which we have reason to believe involves the splitting up of molecules into atoms), is very many times the electromotive force required to liberate the ions from an electrolyte, though the latter progress requires changes in the electrical charges on the ions. These reasons seem to indicate that we can hardly expect to get any clear indication of the charges carried by the atoms in gaseous compounds from the study of the thermal changes which occur when gases enter into chemical combination.

Vapours of Organic Compounds.—These show very interesting differences between the spectra on the two sides of the plate when the discharge passes through them. Thus when the discharge first passes through the vapour of ethyl alcohol, C_2H_6O, the spectrum on the positive side of the plate is the candle spectrum, that on the negative side the carbonic oxide spectrum. For some little time after the discharge commenced I could not detect any hydrogen lines on either side of the plate; after a time, however, they appeared on the negative side but not on the positive. If the discharge was kept running for some time without letting a fresh supply of alcohol into the tube the "candle spectrum" on the positive side of the plate was replaced by the CO spectrum, which now occurred on both sides of the plate accompanied on the negative side by the hydrogen spectrum. This is the appearance presented by all the compounds of carbon, oxygen, and hydrogen which I examined, when the spark had been passing through them for a considerable time, and it is what would occur if the vapour were decomposed by the spark into carbonic acid, water, and hydrogen.

The appearance of the candle spectrum on the positive side of the plate with the CO on the negative was observed in many other cases. Thus on sparking through a tube filled with CO, I could not detect any difference between the spectra on the two sides of the plate, but when a little hydrogen was let into the tube the "candle spectrum" appeared on the positive side of the plate, the carbonic oxide spectrum on the negative. The same effect was observed in a tube filled with cyanogen mixed with a little hydrogen. When the tube was filled with the vapour of methyl alcohol, CH_3OH, the candle spectrum was on the positive side of the plate, the carbonic oxide and hydrogen spectra on the negative; with this vapour, unlike that of ethyl alcohol, I could not detect any stage when the hydrogen spectrum was absent.

The first explanation which occurs to one of this phenomenon is that it is owing to the potential gradient at the negative side of the plate being steeper than that on the positive, so that we may imagine we have a fierce spark on the negative side, a mild one on the positive, and that the fierce spark gives the CO spectrum, the mild one the candle spectrum. There are, however, some phenomena which seem inconsistent with this explanation: in the first place, if the current is reversed after running in one direction, traces of the former spectra linger for some time at the sides of the plates, and, secondly, if the difference is due to the greater decomposition at the negative side of the plate, how is it that in the case of the vapour of ethyl alcohol the hydrogen spectrum is not seen, at the commencement of the discharge, on the negative side of the plate, and only appears after the discharge has passed through for some time, when hydrogen has probably been set free by the decomposition of the vapour by the discharge. If the absence of the candle spectrum from the negative side of the plate is due to the spark being so intense that the hydro-carbon which is supposed to be the origin of this spectrum cannot exist, then we ought to see the spectra of the substances which result from the decomposition of the hydro-carbon, *i.e.* we ought to see the hydrogen spectrum at the negative electrode. The view which seems most in accordance with the results of observations on the discharge through these vapours is that the "candle spectrum" is the spectrum of carbon when the atom is charged with negative electricity, or of some compound of carbon in which its atom is negatively charged, while the "carbonic oxide" spectrum is the spectrum of carbon when the atom is charged with positive electricity, or of some compound in which the carbon atom is positively charged.

Discharge through an Elementary Gas.—It has long been known that when the discharge passes through some elementary gases, the spectra at the two electrodes are different. This was first shown to be the case for nitrogen, then Dr. Schuster showed that the same thing occurred with oxygen, and recently Mr. Crookes has shown that it is also true in the case of argon. I have observed a very striking change in the relative brilliancy of the red and green hydrogen lines at the two electrodes. When the tube with the plate across it was filled with hydrogen at a low pressure, then on the positive side of the plate the red line tends to be brighter than the green, while on the negative side the green line tends to be brighter than the red; in some tubes this was so marked that on the positive side of the plate the red line was bright, and the green invisible, while on the negative side of the plate the green line was bright, and the red invisible. The spectroscope I was using weakened the red rays much more than the green, so that I cannot be sure that the red rays were really altogether obliterated on the negative side of the plate; the above experiment is, however, sufficient to show that on the positive side of the plate the red rays are more easily excited than the green, while on the negative side the green line is more easily excited than the red. On the negative side of the plate we have an excess of positively charged hydrogen atoms, while on the positive side of the plate there is an excess of negatively charged hydrogen atoms, and I am inclined to attribute the difference in the spectra partly at any rate to the difference in properties between a positively and a negatively charged hydrogen atom. The reason I do not attribute it wholly to the difference in the potential gradient on the two sides of the plate is that the effect is not reversed immediately, but only gradually on reversing the coil, the former spectra clinging for some time to the sides of the plate.

Chlorine.—I have made a great many experiments to see if there is any difference between the spectra given by chlorine on the two sides of the plate, but with negative results. Chlorine seems a gas in which we might expect to find this effect, for as Dr. Schuster, in his Report on Spectrum Analysis, says, the behaviour of its spectrum indicates that we have several spectra superposed. I have not, however, been able to affect a separation of its spectra, the differences I observed between the spectra on the two sides of the plate were irregular, and due, I think, to impurities producing effects like those observed when the discharge passes through a compound gas. However, as has been mentioned before, there is even in the case of gases where distinct evidence of separation can be obtained, a region of pressure within which the effects are irregular, and I ascribe my failure to observe separation in the case of chlorine to my having failed to get the relation between the intensity of the discharge and the pressure so adjusted as to get outside this irregular region. The cases, however, in which distinct differences between the spectra of a single gas occur at the two electrodes, seem to indicate that the spectrum given by an element is influenced by the sign of the electrical charge carried by its atoms.

I have made some experiments to determine whether there was any separation produced in a mixture of equal volumes of hydrogen and chlorine kept in the dark, when a considerable difference of potential though not sufficient to produce discharge was maintained between the two electrodes. The parts of the tube adjacent to the two electrodes could be shut off from each other by a tap, and the amount of chlorine in the two sides was determined by absorbing it by caustic potash. The mixture was at atmospheric pressure, and the electrodes were maintained at a potential difference of about 1200 volts by connecting them to a large battery of small storage cells. The potential difference between the terminals was maintained for about sixteen hours on three separate occasions, but on analysing the vessels surrounding the two electrodes, the amount of chlorine in the vessel adjacent

to the negative electrode did not differ from that in the vessel adjacent to the positive electrode by more than 1 per cent., and this could be accounted for by errors of experiments, as test experiments, in which the mixture had not been exposed to the electric field, gave differences comparable with these. We should conclude from the preceding experiments that the molecules of a gas are not acted on by any appreciable translational force tending to move them from one place to another, when they are near to a body charged with electricity. To test this point further, two large terminals were placed in bulbs which were connected by a horizontal capillary tube, in which a drop of sulphuric acid was placed; a difference in the pressure of the gas would cause the sulphuric acid to move, and the arrangement acts as a very delicate pressure gauge. The bulbs and tube were filled with chlorine at atmospheric pressure. The terminals were then connected to the electrodes of a battery giving a potential difference of 1200 volts, but not the slightest movement of the drop of acid could be detected.

I wish to acknowledge the help I have received in making the preceding experiment from my assistant, Mr. E. Everett.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IN the ninth session of Edinburgh Summer Meeting, which was opened by Lord Reay on August 5, and has just concluded, natural science was represented by Elisée Reclus ("On the Evolution of Cities"), Dr. W. W. J. Nicol ("On Every-day Chemistry"), Mr. J. G. Goodchild ("On the Geology of Edinburgh"), Mr. A. J. Herbertson ("On the Geography of the District"), Dr. Louis Irvine ("On the Nervous System"), Mr. J. Arthur Thomson ("On the Biology of the Seasons"), Mr. R. Turnbull ("On Applied Botany"); Prof. Lloyd Morgan lectured "On Evolution Ethics," Prof. Haddon "On the Savage Mind," and Prof. Geddes "On Life and Thought."

MR. JOSEPH BISSETT, who was for two years lecturer at the Agricultural College, Aspatria, has been appointed Agricultural Lecturer to the County of Ayr.

MR. F. G. JONES goes to the Huddersfield Technical School as Lecturer in Physics, Applied Mechanics and Steam, and Mr. J. Brierley is to fill the post of Assistant Master in Chemistry and Physics at the same school.

THE Calendars for the Session 1895–96 of the University College, Bristol, and the Glasgow and West of Scotland Technical College have just been published, and may be obtained, respectively, of Arrowsmith, Bristol, and Anderson, Glasgow.

THE *Educational Times* understands that Mr. Arthur Milman will retire early in 1896 from the Registrarship of London University, under the Civil Service regulation as to age.

SCIENTIFIC SERIALS.

American Meteorological Journal, August.—The principal articles are:—Relation of clouds to rainfall, by H. Helm Clayton. A special study of cloud-forms before and after rain was made at the Blue Hill Observatory, and it was found that the most frequent succession of clouds preceding rain was cirrus, cirro-stratus, alto-stratus, and nimbus; the first which appeared in advance of the rain being usually cirrus. Rain was observed to fall from four classes of clouds: (1) a high cloud sheet (alto-nimbus); (2) a low, ragged cloud sheet (nimbus); (3) long, low rolls of cloud, giving light intermittent showers; and (4) a towering cloud of the cumulus type (cumulo-nimbus). Following rain, the most frequent clouds were strato-cumulus, in long, low rolls, while above there was most frequently cirrus or cirro-stratus. The result of the investigation showed that cloud-forms cannot, in general, be used in predicting rain for more than twenty-four hours in advance, but that, for a few hours in advance, the existence of certain clouds frequently furnish most trustworthy indications of coming rain.—The meteorograph for the Harvard Observatory on El Misti, Peru, by S. P. Fergusson. It has been found impossible to maintain observers at this elevated station (19,300 feet), and during the rainy season, which lasts three or four months, no ascent can be made. A meteorograph, on the principle of Richard's well known instruments, has been constructed at the request of Prof. Pickering, which will work for four months, and will be installed on the summit of the mountain this summer. The record drum revolves once during three days, giving to the paper a speed of three inches in a day, and the paper used for the records is rolled upon a removable reel under the record drum. An illustration of the apparatus is given in the journal.

Bulletins de la Société d'Anthropologie de Paris, 1895, fas. 1. Discussion of the *Pithecanthropus erectus* as the presumed precursor of man, by L. Manouvrier.—This paper contains a critical examination of the remains recently discovered by M. Dubois in Java, upon which an article by Prof. Cunningham has already appeared in NATURE. The dolmen of Ethiau, by M. Lionel Bonnemère. After a careful examination of the marks upon the dolmen, the author has come to the conclusion that they are not due to atmospheric action but to the hand of man.—Lower terrace of Villefranche-sur-Saône, by M. G. de Mortillet. Many worked flints have been found associated with teeth of *Elephas primigenius* and *Rhinoceros tichorhinus*. At Chelles, the molars *E. antiquus* are common and characteristic, and the teeth of rhinoceros, which are very abundant, appear to belong to a small variety of *R. Merkii*.—The engraved stones of New Caledonia, by M. L. Bonnemère. The author exhibited, in the name of M. Glaumont, collector at Coron, a most interesting series of drawings made by him representing certain remarkable objects from the colony. Many large stones are covered with designs that were evidently executed before the European occupation of the island.

L'Anthropologie, 1895, No. 3. General considerations on the Yellow Races, by Dr. E. T. Hamy. The opening lecture of the course of Anthropology at the Museum.—Infantilism, feminism, and antique hermaphrodites, by Henry Meige. Several cases in illustration of this paper have been drawn from the patients of Salpêtrière.—Studies in prehistoric ethnography, by Ed. Piette. Many archæologists have imagined that between the quaternary period and the modern era there was a long interval of desolation, during which the lands of Western Europe were devoid of inhabitants, and the record of human life was interrupted. They named it the *hiatus*. The author traces the history of the harpoon during this period, and shows that no such *hiatus* occurred. Sculpture in Europe before the Greek-Roman Influences, by M. Salomon Reinach. In this section of M. Reinach's valuable monograph, the subject of gesture is treated, and numerous illustrations of bronze figures are given in illustration of the author's argument.

Bollettino della Società Sismologica Italiana, i., 1895, No. 4.—Vesuvian notices (1894), by G. Mercalli.—On the propagation in Italy of the Lubiana earthquake of April 14, 1895, by M. Baratta. A brief account, with a map showing the course of the isoseismal lines in Italy.—Notices of Italian earthquakes (April 1895). A valuable list of records, principally of the earthquake which forms the subject of the preceding paper.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 20.—"On the Refractive Index of Water at Temperatures between 0° and 10°." By Sir John Conroy, Bart., F.R.S.

In 1856, Jamin (*Comptes rendus*, vol. xliii. p. 1191) published an account of observations he made on the refractive index of water at temperatures between 30 and 0°. He used an interference method, and found that as the water cooled the index increased; similar results have been obtained by other observers, but although it appears to be proved that the refractive index of water increases with the decrease of temperature until the freezing point is reached, few determinations of the values of refractive indices of water near its point of maximum density have been published.

The method employed was the ordinary one, the determination of the angle of minimum deviation for a ray of definite wave-length passing through a hollow glass prism containing water at a known temperature.

The prism was filled with distilled water which had been recently boiled and allowed to cool under reduced pressure, and

was surrounded by a water-jacket, through which a stream of brine, cooled by a freezing mixture, could be passed.

The determinations were made exclusively with sodium light. In the first column of the table the values of the refractive indices, relative to air, for each degree are given to five places; in the second the values as found by Walter, and in the third and fourth those for sodium light, given by Gladstone and Dale, and Rühlmann.

Refractive Indices of Water.

t.	C.	W.	t.	G and D.	t.	R.
°			°		°	
0	1·33397	1·33401	0·0	1·33374	0·0	1·33375
1	1·33397	1·33400	4·0	1·33367		1·33380
2	1·33396	1·33398	6·5	1·33356	1·5	1·33375
3	1·33394	1·33396	9·0	1·33342	4·0	1·33372
4	1·33392	1·33393	—	—	5·0	1·33371
5	1·33389	1·33390	—	—	5·8	1·33368
6	1·33385	1·33387	—	—	9·9	1·33355
7	1·33382	1·33383	—	—	10·0	1·33353
8	1·33378	1·33379	—	—	—	
9	1·33375	1·33374	—	—	—	—

The values show that the refractive index of water, as was first announced by Jamin, increases continuously up to the freezing point, the rate of increase, however, seems to change about 4°, the temperature of maximum density, as was pointed out by Gladstone and Dale, and that no formula representing the variation of the refractive index of water with the temperature, as a function of the density only, can be a complete expression of the facts of the case.

PARIS.

Academy of Sciences, August 26.—M. Fizeau in the chair. Truffles (*Terfas*) from Cyprus (*Terfezia Claveryi*), Smyrna, and La Calle (*Terfezia leonis*), by M. Ad. Chatin.—Observations of Swift's comet (August 20, 1895), made at Lyons Observatory by means of the coudé equatorial (0·32 m.), by M. G. Le Cadet. The remark is recorded that this comet appears as a very diffuse and feeble nebulosity almost equally spread in every direction. By oblique vision a nearly central feeble condensation can be distinguished.—Observations of the planet Phaeo (—), made at Marseilles Observatory by means of the 0·26 m. equatorial, by M. Borrelly.—On regular pencils and the *équitentes* of the *n*th order, by M. Paul Serret.—Heat of solution and of formation of sodium and potassium cyanurates, by M. Paul Lemoult. A detailed thermochemical study. The difficulty of forming the trimetallic salts is emphasised, and it is shown that the sodium and potassium series do not differ essentially. Water does not appear to decompose these salts.—On *apiculé* fermentation, and on the influence of aeration in elliptic fermentation at a high temperature, by MM. M. Rietsch and M. Herselin. Alcohol formed from *apiculé* yeasts requires more sugar for its production than that produced by the agency of elliptic yeasts. Cooling the must to just below 30 and aeration both favour the economical production of alcohol.—On aluminium utensils, by M. Balland. These utensils in ordinary camp use stand wear fairly well, and are not much attacked by foods during the short time they are in contact therewith. They should not be soldered or brought into contact with other metals. In the process of manufacture, treatment with soda should be avoided; the fine matt surface produced is more easily attacked than a polished surface.—On the rôle of the liver in the anticoagulant action of peptone, by MM. E. Gley and V. Pachon. The results of the authors' experiments appear to show that peptone does not itself exert any anticoagulant effect, but that it stimulates the production by the liver of some substance possessing anticoagulant properties.—The ellipsoidal stethoscope, by M. Ch. V. Zenger. A solid homogeneous wooden ellipsoid of revolution is cut by two planes perpendicular to the principal axis, and passing through the two foci. One flat end being placed as usual on the body surface, the ear perceives at the other focus the sounds of organ movements with remarkable intensity, and free from parasitic sounds formed in the air space of the ordinary instrument.—The electrodynamic system of the world, by M. Ch. V. Zenger.

GOTTINGEN.

Royal Society of Sciences.—The *Nachrichten*, part 2 for 1895, contains the following memoirs of scientific interest:—

May 25.—O. Holder: On groups whose order is free from squares.

June 15—A. Hurwitz: A fundamental theorem in the arithmetical theory of algebraic magnitudes. A. von Koenen: On the selection of points near Gottingen at which differences in the intensity of gravity may be expected in trial pendulum experiments. W. Schur: On the results of the first pendulum trials. W. Voigt: *In memoriam* F. E. Neumann.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Annual Report of the Department of Mines and Agriculture, N.S.W., for the Year 1894 (Sydney).—Diseases of Personality: Prof. Ribot, translated (Chicago, Open Court Publishing Company).—Analytical Key to the Natural Orders of Flowering Plants: F. Thonner (Sonnenschein).—Studies in the Evolutionary Psychology of Feeling: H. M. Stanley (Sonnenschein).—University College, Bristol, Calendar for the Session 1895-1896 (Bristol, Arrowsmith).—Origin of Plant Structures: Rev. G. Henslow (K. Paul).—Bourne's Handy Assurance Manual, 1895: W. Schooling (London).

PAMPHLETS.—Stenopaic or Pin-hole Photography: F. W. Mills and A. C. Panton (Dawbarn).—University Correspondence College, Lon. Inter. Science and Prel. Sci. Guide, No. vii. (Red Lion Square). Ditto Inter. Arts Guide, No. x. (Red Lion Square).

SERIALS.—Indian Museum Notes, Vol. 3, Nos. 4 and 5 (Calcutta).—Chambers's Journal, September (Chambers).—Contemporary Review, September (Isbister).—Good Words, September (Isbister).—Sunday Magazine, September (Isbister).—Humanitarian, September (Hutchinson).—National Review, September (Arnold).—Scribner's Magazine, September (Low).—Fortnightly Review, September (Chapman and Hall).—Clinical Sketches, No. 8, Vol. 2 (Smith, Elder).—Notes from the Leyden Museum, July (Leyden, Brill).—Journal of the Royal Microscopical Society, August (Williams and Norgate).—A Monograph of the Land and Freshwater Mollusca: J. W. Taylor, Part 2 (Leeds, Taylor).—Bulletin de l'Académie Royale des Sciences de Belgique, 65e Année, No. 7 (Bruxelles).—Zeitschrift für Physikalische Chemie, xvii. Band, 4 Heft (Leipzig).—Katalog der Bibliothek der K. Leopoldisch-Carolinischen Deutschen Akademie der Naturforscher, Sechste Liefg. (Halle).—Ditto Repertorium zu den Acta und Nova Acta der Akademie, Erster Band (Halle).—The Asclepiad, No. 43, Vol. xi. (Longmans).

THURSDAY, SEPTEMBER 12, 1895.

A NEW STANDARD DICTIONARY.

A Standard Dictionary of the English Language. Vol. ii. Prepared under the supervision of Dr. I. K. Funk, Dr. F. A. March, and Dr. D. S. Gregory. (New York and London: Funk and Wagnall Co., 1895.)

SINCE the appearance of the first volume of this work, noticed in NATURE, vol. l. p. 146, we have often had occasion to refer to it. and have formed opinions as to its merits and faults. In many respects the dictionary is a very good one within its compass, though it does not contain much that is really new.

Before going further, it may be well to state briefly the magnitude of the work, and to give a general idea of its characteristics. The two volumes run into 2338 pages and contain 301,865 vocabulary terms, embellished by 5000 illustrations. A point upon which great stress is put is that more than two hundred editors and specialists have assisted in the production of the work, though it is not clear to what extent this assistance was given. Their services, with those of the five hundred readers for quotations, who are said to have been engaged upon this work, have helped to bring the cost up to one million dollars! Considering how little there is in the dictionary that is not in the "Century," "International," and other American dictionaries, one wonders where the money has gone. This, however, is by the way, and we only mention the matter because the large amount stated to have been spent in the production of the dictionary is put forward as a claim to favour.

A few definitions from the work will be the best means of indicating its merits. A whole column of the dictionary is taken up with definitions, and examples, of the use of the word science and its synonyms. The first two of the six definitions given are as follows:—

Science.—(1) Knowledge gained and verified by exact observation and correct thinking, especially as methodically formulated and arranged in a rational system; also, the sum of universal knowledge.

(2) Any department of knowledge in which the results of investigation have been worked out and systematised; an exact and systematic statement of knowledge concerning some subject or group of subjects; especially, a system of ascertained facts and principles covering and attempting to give adequate expression to a great natural group or division of knowledge.

The sciences are divided in the dictionary into (1) the mathematical, treating of quantity; (2) the physical, treating of matter and its properties; (3) the biological, treating of the phenomena of life; (4) the anthropological, treating of man; and (5) the theological, treating of the Deity. All the divisions are fully treated under their respective heads. Thus, under physical sciences, the classification of them as sciences of energy is given; the biological sciences are fully tabulated and their relation to one another shown with all their sub-divisions, and anthropology is made to embrace all the sciences relating to man. The departments of anthropology presented in the dictionary are (*a*) Somatology, (*b*) Ethnology, (*c*) Archæology. It is worth while printing the definition of the third of these for the benefit of unscientific archæologists.

Archæology.—The science of antiquities; in its widest sense, the branch of anthropology, embracing archæography, concerned with the systematic investigation of the relics of man and of his industries, and the classification and treatment of ancient remains and records of any or every kind, whether historic or prehistoric, of ancient places, customs, arts, &c.

In popular signification, archæology refers mainly to the collection or investigation of the materials from which a knowledge of the particular country under investigation may be obtained, which materials may be divided into *written*, *monumental*, and *traditional.* Scientific archæology is (1) general, including (*a*) the geology of the epoch of man and (*b*) the prehistoric ages; and (2) special, including the study of separate nations and areas.

These examples, which could be multiplied many times, are sufficient to show the generally trustworthy character, and the fulness, of the definitions, so far as science is concerned. The work has an attractive appearance, and offers every facility for consultation, and is altogether a desirable addition to a library.

THE CHEMISTRY OF LIGHTING.

Chemical Technology, or Chemistry in its Applications to Arts and Manufactures. Edited by C. E. Groves, F.R.S., and W. Thorp, B.Sc. Vol. ii. Lighting. (London: J. & A. Churchill, 1895.)

THE second volume of this important work possesses great intrinsic worth. Section i., dealing with fats and oils, by W. Y. Dent, contains much information concisely and clearly expressed. It may be noted that, in connection with the determination of specific gravity, the Sprengel tube is described, but no mention is made of the modification of this apparatus having the capillary arms at right angles and provided with expansion bulbs, although the latter form would always be used where accuracy combined with ease of manipulation were desired. When specific gravities are given to four significant figures, correction to a vacuum is necessary, or the fourth figure has no meaning. No mention is made of this in the text, and the specific gravities given are termed densities, a misuse of the latter term which occurs much too often.

The second Section, on stearine, by J. McArthur, puts forth the main processes for the decomposition of fats in a very explicit form. The writer wisely confines the term "saponification" to decomposition by means of a base.

The account of the candle manufacture, by L. and F. A. Field, given in Section iii., is highly interesting, and will be read with profit by many who have no connection with such matters, as well as by specialists. Producers of gas may well believe that their product will be in increasing demand when the candle industry flourishes in spite of the introduction of later forms of lighting. Doubtless candles owe their present hold on the public favour largely to the great improvements in quality effected by recent advances in the methods of manufacture. How great these advances are may be gathered from even a rapid perusal of the pages before us.

The description, in Section iv., of the petroleum industry, by Boverton Redwood, is both graphic and

complete. It forms the best monograph on the subject yet written. The origin of petroleum is so treated as to present the various theories put forward to account for its occurrence; necessarily, no authoritative decision can be given on this very debatable question. Concerning the occurrence of sulphur in the petroleums from Ohio and Canada, those interested would do well to supplement the bare mention of the fact here given by reference to the July number of the *Journal* of the Franklin Institute, where C. F. Mabery gives an account in which the subject is treated as its importance requires. Warren is stated by Mr. Redwood to have isolated hydrocarbons of the C_nH_{2n} series, termed naphthenes by Markownikoff. Mr. Mabery shows that the Ohio and Canadian petroleums do not yield the naphthenes of Markownikoff and Ogloblin, but give hydrocarbons of the C_nH_{2n+2} series of similar boiling points. This writer also proves conclusively the presence of benzene, toluene, and xylenes in these petroleums.

The manufacture of shale oil gives yet another instance of the application of continuous processes; the text contains very lucid descriptions of these, well and sufficiently illustrated. Few of the general public can have any adequate conception of the number and variety of lamps in existence for use with oils. An exhaustive account is given of these, and the advantages or disadvantages characteristic of the main types of oil-lamps are dwelt upon at sufficient length to enable an intelligent judgment to be formed as to the suitability of any particular lamp for the work required from it.

The Section on safety-lamps, with which this volume concludes, has been contributed by D. A. Louis, in conjunction with Boverton Redwood. It gives by no means the least interesting reading. Although the excellent account of the lamp-indication of fire-damp is highly technical, and calculated to be eminently useful to specialists, the general reader will find no difficulty in grasping the principles involved, and will much appreciate the clearness with which this important subject is treated.

It may be hoped that the high standard exhibited in this volume will be maintained in volume iii., announced as to appear shortly. The editors are certainly to be congratulated on the excellent production now before us.

W. T.

OUR BOOK SHELF.

Science Readers. By Vincent T. Murché. Book iv. Pp. 216. (London: Macmillan and Co., 1895.)

THE conversational method of instruction, which used to be so general in school books, is not one that leads to pleasant memories. Mr. Murché has created two boy prodigies in his "Science Readers," and they ask and answer questions of a teacher whose laudable ambition is to elicit and impart all kinds of scientific knowledge upon every suitable or unsuitable occasion. We reverence that teacher for his patience and for his ability to find texts in everything. The pity of it is, that lessons given in this way on all and sundry topics lack the quality which lies at the base of all true scientific knowledge, viz. the orderly arrangement of facts. A lesson on solids, liquids, and gases precedes one on our bodies, another on gravity precedes a lesson on vertebrates and invertebrates. A lesson on the classification of invertebrates is wedged between two on hydrostatic pressure, and so on throughout the book. Possibly the variety is introduced to charm the youthful mind, but it is not a desirable attribute of the book; for the method must result in the acquisition of unconnected information, and such knowledge has little to commend it. In the matter of illustration, and simplicity of language, the book leaves little to be desired.

A Garden of Pleasure. By E. V. B. Pp. 220. (London: Elliot Stock, 1895.)

A FEW chapters fresh with the fragrance of common country flowers, and breathing the life of "lustrous woodland." Here and there the authoress lapses into sentiment, but, taken as a whole, her language is attractive in its simplicity. The changes that go on in organic nature from month to month are drawn with careful touch, and many students of botany would derive benefit from the contemplation of the sketches.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The "4026·5" Line and D_3.

MAY I call attention to the fact that the line at 4026·5, now recognised as belonging to the spectrum of helium, and conspicuous in the Orion stars, is also prominent in the spectrum of the solar chromosphere. Although not given in the catalogue of chromosphere lines (which dates from 1872), it was observed and published as long ago as 1883 (*Am. Jour. Sci. and Art.*, November 1883), in connection with another line at 4092, seen at the same time. Since then the 4026 line has been observed repeatedly, and might be given a place in the catalogue with a relative frequency of about 15, and a brightness of 3 or 4. Like the other helium lines it has no dark analogue in the ordinary solar spectrum. The 4092 line falls upon a strong double line shown upon Rowland's map, but I am not sure to which of the two components it belongs; it is faint, and seldom seen.

While D_3 rarely appears as a dark line upon the solar spectrum, yet in the course of over twenty years I am able to count up a considerable number of instances; certainly not less than twenty or thirty. The phenomenon occurs usually in the penumbral region of an active sun-spot, which in its nucleus reverses the lines of hydrogen, magnesium, and sodium, and sometimes D_3 itself. By a slight motion of the telescope as one passes away from the nucleus, it crosses regions where D_3 appears as a smoky shade: on page 130 of "The Sun" I have figured a typical case.

I have not yet been fortunate enough to see the duplicity of D_3 myself, but Prof. Reed has observed it on several occasions.

Hanover, N.H., August 26. C. A. YOUNG.

On the Temperature Variation of the Thermal Conductivity of Rocks.

NATURE reproduces the results obtained by Lord Kelvin, P.R.S., and J. R. Erskine Murray, a paper read at the Royal Society, May 30, "On the Temperature Variation of the Thermal Conductivity of Rocks." These gentlemen arrived at the following results: "(§ 13). . . . that for slate with lines of fluor parallel to cleavage planes, the mean conductivity in the range from 123° C. to 202° C. is 91 per cent. of the mean conductivity in the range from 50° C. to 123° C., and for granite the mean conductivity in the range from 145° C. to 214° C. is 88 per cent. of the mean conductivity in the range from 81° C. to 145° C."

These results are so widely different from those I obtained by another method, and which Lord Kelvin had the kindness to publish in NATURE, March 7, 1895, p. 439, that I must be allowed to introduce here a word of objection.

It seems to me that details of experimental dispositions are important enough, and should be trustworthy. It is however, not opportune to discuss them minutely now.

The experimenters based their work on the case of Fourier's

"indefinite wall," which is characterised by the fact that temperature differences in the parallel planes are exactly proportional to the distances of these planes. According to the experiment, they get the result that this proportionality does not exist, and that conductibility varies much according to temperature.

In my opinion, this absence of proportionality arrived at, proves rather that the experimental conditions were defective, and are in contradiction with the hypothesis of the "indefinite wall" case.

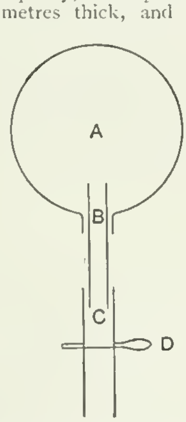
I admit, in principle, the employed method, but I think it should be modified until—for the same temperature of the bath, the said proportionality should be obtained; then, in a new experiment, the temperature of the bath being higher, it should be verified if the proportionality and the conductibility remain, or if the last increases or diminishes with the temperature.

Neuchâtel, August. ROBERT WEBER.

Experimental Mountain-building.

PROF. JOHANNES WALTHER, of Jena, requests me to communicate to you the following details regarding an interesting experiment which he has recently devised for teaching purposes: it is intended to explain mountain-formation.

He compares the system of folds on the surface of our slowly-ageing earth to the wrinkles which form on the skin of a drying apple, and points out that the height of our mountain-chains in relation to the mass of the globe is precisely comparable to the wrinkles on the skin of the apple. In order to demonstrate the formation of these folds, he takes an indiarubber balloon (A), and attaches to it a bit of glass tubing (B). On to this is stretched a piece of indiarubber tubing (C), which is pinched close by the stopcock (D). When the indiarubber balloon is blown out to its full capacity, it is spread over with a layer of flour-paste two millimetres thick, and is then dipped and



twirled round and round in dry wheaten flour until a perfectly smooth crust, three to four millimetres in thickness, covers the whole sphere. The balloon is then placed on a tripod, so that the indiarubber tubing (C) dips exactly into a glass of water standing below. Thereupon the stopcock is turned open, and the air is allowed to escape in single bubbles: the volume of the ball is lessened, and lateral pressure makes itself immediately felt in the paste-crust. Small folds gradually grow bigger, single folds unite to form systems of folds, flat areas of depression sink deeper and deeper, and the neighbouring folds twirl and cross over the depression. The features of the Cordilleras, of the Jura, and many other well-known tectonic relations are thus reproduced with striking accuracy. Whenever it is desired to repeat the experiment, one need simply blow the balloon out again, smooth out the folded surface by dipping and twirling in dry flour, and all is ready for another demonstration.

London, August 26. L. BELINFANTE.

Joseph Thomson.

IN Mr. Gregory's sympathetic notice (NATURE, p. 440) of Joseph Thomson, he hardly does justice to the memory of the deceased traveller in relation to the scientific results of his expeditions; at least so far as botany is concerned. During his too short career Thomson presented three considerable collections of dried plants to Kew. The first, which appears to have been made on his own initiative, chiefly between Lake Nyassa and Lake Tanganyika, was secured for Kew in 1880, through the instrumentality of the late Colonel J. A. Grant, F.R.S. This was not the subject of a special paper: yet it contained a number of interesting novelties, some of which have from time to time been published in Hooker's "Icones Plantarum" and elsewhere. Before going out again Thomson carefully studied the means by which his collecting opportunities might be turned to the greatest advantage. Armed with this knowledge he collected even more successfully in the Kilimanjaro and other mountains of Eastern Equatorial Africa. This second collection reached Kew in September 1884, and proved of the greatest scientific importance, being the first adequate illustration of the mountain flora of that region. It contained scarcely 150 species; but the specimens were selected with admirable judgment, and were sufficient for all purposes. It was worked out by Sir Joseph D. Hooker and Prof. D. Oliver, and the very important results recorded in the twenty-first volume of the *Journal* of the Linnean Society. This paper and Thomson's collection will always rank among the classical documents for the study of the phytogeography of Central Africa. Subsequently Mr. Thomson sent to Kew the botanical fruits of his journey to the Atlas Mountains, and although they contained very few previously unknown plants, they were none the less instructive as a sample of the flora of that comparatively little-known part of the world. Had he preserved his health Thomson might have taken his place in the first rank of botanical explorers. He had acquired the rare gift of selection in collecting; of knowing what to secure and what to neglect.

W. BOTTING HEMSLEY.

Late Nestlings.

TO-DAY I observed nests of the house-martin underneath the eaves of the clock-tower at Lamlash Pier, on the south and west sides. The parents were busy feeding their young, whose cries I heard. Surely this is a late date for a migratory bird. How are these nestlings to get across the ocean? JAS. SHAW.

Barrhead, September 7.

THE INSTITUTE OF FRANCE.

IN a few weeks, at the end of October, the Institut National de France is to celebrate its first centenary. Some words concerning its origin and organisation may be of interest at the present moment.

The Institute is the outcome of a previous scientific society, entirely due to individual initiative. During the first half of the seventeenth century, a few men, between whom love of science was a firm bond, agreed to meet at regular intervals at the house of one of their number, informally, in order to exchange views, to keep each other posted up on their various researches, and to make up an unconventional assembly of congenial spirits. It was more of a temporary or intermittent club than a real society, as we understand the latter now. These men were mostly mathematicians and physicists—for at that time natural science was more in the *werden* than in the *sein* state—and Mersenne, Descartes, Blaise Pascal, Gassendi, are some of them. Their meetings soon attracted public attention, and the great Colbert, anxious for the development of the arts of peace after the Pyrenees treaty had put an end to the war, considered them as being of sufficient importance and utility to take an interest in them, and to support the incipient society officially.

Colbert even made out a full plan of what was to be realised 200 years later; what he organised was a body of scientific men who were to meet at regular intervals, and were divided into three classes—historical scholars, literary men, and, finally, scientific men. The private society of mathematicians and physicists grew into the Académie des Sciences, and each of the three academies met separately in the Bibliothèque du Roi, at Colbert's own residence. The king, as a sign of his approval, gave some money for experiments, and some pensions.

Among the members (no one knows how they were appointed) were Huyghens, Mariotte, Pecquet, Picard, Roberval. The Academy of Sciences, the Académie Française, and the Académie des Inscriptions et Médailles thus lived in harmony, each having its particular pursuits. The history of these academies would take too much space; it is enough to have shown how they originated. They lived on till the Revolution, when they were organised on a new basis, and the Institute came into existence. The whole constitution of France being altered, that of the academies had also to be changed.

The Institute was founded in 1795. Article 298 of the *Constitution du 5 Fructidor, an* iii. (August 22, 1795) gave it the mission of "registering discoveries, and perfecting arts and sciences," while later laws provided for the details of the scheme, that of the 3 *Brumaire, an* iv., *i.e.* October 25, 1795. According to this law, the Institut National—a new name applied to, practically, an old thing—was divided into three classes—scientific (10 sections); moral and political (6 sections); literary and artistic (8 sections). Bonaparte (3 *Pluviose, an* xi., January 23, 1803) altered this plan, and added a fourth class, so that the Institute comprised the class of mathematical and physical sciences, with 11 sections; that of French language and literature (no sections); that of ancient language and literature (no sections); and that of fine arts (5 sections). In 1816, upon the return of monarchy, the general plan was respected, but in 1832 a fifth class was added: that of moral and political sciences, which had disappeared in 1803. Those five classes still exist, under the names of Académie Française, Académie des Sciences, Académie des Beaux-Arts, Académie des Sciences Morales et Politiques, Académie des Inscriptions et Belles Lettres. They still dwell in the Palais des Quatre Nations on the Seine, where Bonaparte housed them in 1805.

At present, the Institute is a society of men of eminence, divided into five distinct sub-societies, or academies, each member being at the same time, and as a matter of course, member of this or that particular academy, and of the Institute as a whole. Each academy has its definite purpose, and meets each week on fixed and different days; the Institute, as a whole, meets once a year, in October.

As a whole, the Institute is regulated by a committee of delegates, elected by, and in, the five academies, while each academy has its own president and secretary.

Two points must be noticed in reference to the academies. The one is that the Académie de Medécine has nothing at all to do with the Institute; it is a separate society of medical men only (quite distinct, without the slightest relationship to any of the above-mentioned academies, or to the Institute. The other is that there is no connection whatever between the Institute or academies which make up the Institute, and the title of Officier d'Académie. To be Officier d'Académie is to have received from the Department of Public Instruction a special decoration (of the *Palmes Académiques*) which is, theoretically at least, more specially destined to persons who serve the cause of education and instruction. The Officiers d'Académie are thousands in number; they have nothing at all to do with the Academies.

Now, as to the membership of the latter.

New members are always elected by the members of each academy. A man considers himself as eligible for such or such academy; all he has to do, when a vacancy occurs in the academy or in the section to which he should belong, considering his previous work, is to declare himself a candidate by a letter addressed to the president of the latter, and to prepare a pamphlet in which he gives the list of his scientific or literary titles, of his works, of his researches or discoveries, of the functions he has occupied, &c.; and this pamphlet he sends or carries to each of the members of the academy. It is customary for every candidate to pay a visit to each of the latter, and then he waits for the result; in the meantime canvassing, in order to secure this or that member's vote when things do not seem to run smoothly. A very amusing book might be written of the anecdotes which are current upon the devices suggested to the candidates by what is called the "green fever," *la fièvre verte*, the fever which takes hold of a man anxious to wear the green-laced uniform which the members of the Institute wear upon official occasions. But such a book could be published only after the death of the author and of those concerned. Generally speaking, however, the Académie des Sciences would contribute little to the making of this book. Each election must be approved by the President of the Republic, and is approved as a matter of course. Each member receives a small *indemnité* of £60 a year.

Each academy has a limited number of members, but in most academies there are different classes of membership. The Académie Française, for literary men, comprises 40 immortals all told, one of whom is perpetual (life) secretary. It has no associates nor corresponding members, and while the members have little or nothing to do as members, save the preparation of a dictionary, and examining works which compete for various prizes, it is the custom for each new member to deliver a very elaborate speech concerning his predecessor, and one of the members answers this *discours de réception* by a speech concerning the works of the new-comer.

The Académie des Inscriptions et Belles Lettres, for men who deal specially with history, comprises 40 members (of whom one is life-secretary), 10 free members, 8 foreign associates, 30 foreign and 20 national corresponding members. Among the foreign associates are Prof. Max Müller, Sir Henry Rawlinson, W. Stokes; among foreign corresponding members, Mr. R. S. Poole, Sir J. Evans, M. A. Neubauer, Sir E. M. Thompson.

The Académie des Beaux-Arts is divided into five sections (painting, sculpture, architecture, engraving, music), and comprises 41 members (one of whom is life-secretary). There are besides 10 free members, 10 foreign associates, and 50 correspondents. Among the associates are Sir J. E. Millais, Sir F. Leighton, Mr. Alma Tadema; among the corresponding members, Prof. H. Herkomer, Sir E. Burne-Jones, Mr. Waterhouse, Mr. R. W. Macbeth.

The Académie des Sciences Morales et Politiques is divided into five sections (philosophy, morals, law, political economy, history), and comprises 40 members (of whom one is life-secretary), 16 free members, 6 foreign associates, 48 corresponding members. Among the foreign associates are Right Hon. W. E. Gladstone and Mr. Henry Reeve; Mr. Robert Flint, Right Hon. J. Bryce, Sir Fredk. Pollock, Right Hon. G. J. Goschen, Bishop Stubbs, and Mr. Lecky are corresponding members.

Last, but by no means least, comes the Académie des Sciences, which certainly exerts the largest influence, and is the most highly considered in public opinion. Divided into eleven sections, it comprises 68 members (of whom two are life-secretaries), 10 free members, 8 foreign associates, 100 corresponding members. Lord Kelvin, Sir Joseph Lister, and Dr. E. Frankland are among the associates. The British Correspondants are as follows:—Mathematical sciences (geometry: Prof. J. J. Sylvester, Rev. Prof. Salmon; astronomy: Dr. J. R. Hind, Mr. Norman Lockyer, Dr. W. Huggins; geography and navigation: Sir George Henry Richards; general physics: Sir G. G. Stokes, Lord Rayleigh. Physical sciences (chemistry: Prof. A. W. Williamson, Sir Henry Roscoe, Prof. W. Ramsay; mineralogy: Dr. J. Prestwich, Sir A. Geikie; botany: Sir Joseph D. Hooker, Dr. Maxwell Masters; rural economy: Sir J. B. Lawes, Sir J. H. Gilbert; anatomy and zoology: Sir W. Flower;

medicine and surgery: Sir James Paget. Prof. Huxley was a corresponding member also.

Each academy has more or less money left to it in order to distribute prizes for different subject-matters; the Académie des Sciences and Académie Française are the richest. The Duke d'Aumale has agreed to leave the splendid residence of Chantilly, with the books and collections it contains, to the Institute, and this handsome gift is accompanied by a sum of money to help to keep the castle in good order. It is estimated that, all paid, the Institute will be 100,000 francs richer each year for this gift.

English corresponding members and associates will have a good opportunity of visiting the fine chateau of Chantilly, for on October 26 the Duke opens the doors to all members of the Institute, and bids them welcome. The celebration of the centenary, to which *all* members of each Academy, *all* corresponding members and associates in every country have been, or are being, invited, will last four days. The programme has been given in NATURE (August 8) in full. The only new feature I can introduce, is the programme of the afternoon performance at the Comédie Française, where the best actors of the best theatre in France will play *Les Horaces* (Corneille), *Les Femmes Savantes* (Molière), and recite a piece of poetry by Sully-Prudhomme. The railway fares will be reduced 50 per cent. for all foreigners invited.

All may be sure to receive a hearty welcome. If the Institut de France does not contain *all* our "best men" in the different departments of knowledge or art, it contains only men of recognised authority. They are men whose aims are noble, and their feelings can but be most cordial towards those whose aims are the same towards their fellow-workers, whatever language they speak, whatever country they come from, towards all whose work and character are high enough to have secured for them the highest recognition French science can award.

HENRY DE VARIGNY.

THE IPSWICH MEETING OF THE BRITISH ASSOCIATION.

Coming after the Oxford year, the meeting at Ipswich is in numbers a comparatively small one; but, from a scientific point of view, everything augurs well. The papers promise to be of more than usual interest, and are so numerous that most of the Sections will have to sit early and late in order to get through all the work before them.

We have previously referred at some length to the work proposed for Sections A, B, C, D, G, and H.

Section D is this year reserved entirely to zoology and animal physiology, under the presidency of Prof. W. A. Herdman.

Prof. A. C. Haddon will read a paper on the exploration of the isles of the Pacific. Dr. Bashford Deane, of New York, is to read two papers—one on an apparatus for catching oyster spat, the other on the ganoids of North America. Prof. McIntosh will open a discussion on British fisheries. A paper will be read by the Rev. T. R. R. Stebbing, on zoological nomenclature and publication. Special interest is likely to be taken in a paper by the President and Prof. Boyce on the subject of oysters and typhoid, by those who propose to join in the excursion to the Colne Oyster Fishery (Colchester), which has just been added to the programme for Wednesday. It is intended to make a large use of the lantern for illustrating papers in the Section.

The provisional programme in Section E (Geography) makes it evident that the Section is, as usual, to be a popular one. After the address of the President, Mr. H. J. Mackinder, an account will be given, by Mr. H. S. Cowper, of a journey over Tarhuna and Gharian in Tripoli; and Mr. J. Batalka-Reis will discuss how to consider and write the history of the discovery of the world. On Friday, the papers will be given by Mr. C. E. Borchgrevink, describing his voyage to the Antarctic Sea; by Mr. H. N. Dickson, on oceanographical research in the North Sea; by Mr. W. B. Blaikie, on the cosmosphere; and by Mr. John Dodd, on Formosa. On Monday, Mr. E. G. Ravenstein will present a report on the climate of tropical Africa; and there will be papers by Mr. G. F. Scott Elliot, on Ruwenzori and East Africa; by Captain S. L. Hinde, on the Congo State; by Mr. J. T. P. Keatly, on the port of the Upper Nile in relation to the highways of commerce; and by Mr. J. L. Myres, on the maps of Herodotus. On Tuesday, Mr. Weston will deal with the New Zealand Alps, and Mr. J. L. Myres with Asia Minor, whilst Mr. A. Trevor Battye will give an account of Kolguev.

In Section F (Economic Science and Statistics), over which Mr. L. L. Price presides, bimetallism appears early on the scene, the arrangement being to devote Friday morning to a monetary discussion, in which representatives of the Bimetallic League and of the Gold Standard Defence Association, and others, are expected to take part. Monday will be given up to a discussion on the state of agriculture, on which question Captain E. G. Pretyman, M.P., will read a paper from the landlord's point of view, and Mr. Herman Biddell one from the tenant's point of view. This discussion has unfortunately been fixed for the same day as the discussion on the relation of chemistry to agriculture in Section B, but it is hoped that by an arrangement of the hours the two discussions may not clash. Other contributions in Section F will be by Mr. H. W. Wolff, on land banks; Mr. H. Moore, on co-operation in agriculture; Mr. E. Cannan, on population; Mr. H. Higgs, on the climbing ratio; and Rev. Frome Wilkinson, on the State and the labourer.

In Section H (Anthropology), in which Prof. W. M. Flinders Petrie presides, ethnology is to play a prominent part. The Section will, therefore, feel all the more the absence of Mr. E. W. Brabrook, who is unable to come to Ipswich on account of the very sad bereavement he has so recently suffered. It has been arranged that the Section shall sit each morning till 12.30 or 1, and then reassemble at 2, on each day except Saturday for a lecture illustrated by the lantern.

Botany is sitting for the first time as a distinct Section (K), under the presidency of Mr. W. T. Thiselton-Dyer. Amongst the papers will be one on Sporangia by Prof. F. O. Bower. Dr. D. H. Scott will speak on fossil botany, with special reference to the researches of the late Prof. Williamson. A paper on fossil botany will also be read by Prof. Solms-Laubach, of Strasbourg. Prof. E. C. Hansen, of Copenhagen, promises a paper on the variation of yeast cells, and Mr. A. C. Seward one on the Wealden Flora. Amongst other foreign botanists attending the meeting is Dr. T. M. Treub, of Java. A special botanical excursion, not figuring as one of the regular excursions, is being arranged.

INAUGURAL ADDRESS BY SIR DOUGLAS GALTON, K.C.B., D.C.L., F.R.S., PRESIDENT.

My first duty is to convey to you, Mr. Mayor, and to the inhabitants of Ipswich, the thanks of the British Association for your hospitable invitation to hold our sixty-fifth meeting in your ancient town, and thus to recall the agreeable memories of the similar favour which your predecessors conferred on the Association forty-four years ago.

In the next place I feel it my duty to say a few words on the great loss which science has recently sustained—the death of

the Right Hon. Thomas Henry Huxley. It is unnecessary for me to enlarge, in the presence of so many to whom his personality was known, upon his charm in social and domestic life; but upon the debt which the Association owes to him for the assistance which he rendered in the promotion of science I cannot well be silent. Huxley was pre-eminently qualified to assist in sweeping away the obstruction by dogmatic authority, which in the early days of the Association fettered progress in certain branches of science. For, whilst he was an eminent leader in biological research, his intellectual power, his original and intrepid mind, his vigorous and masculine English, made him a writer who explained the deepest subject with transparent clearness. And as a speaker his lucid and forcible style was adorned with ample and effective illustration in the lecture-room; and his energy and wealth of argument in a more public arena largely helped to win the battle of evolution, and to secure for us the right to discuss questions of religion and science without fear and without favour.

It may, I think, interest you to learn that Huxley first made the acquaintance of Tyndall at the meeting of the Association held in this town in 1851.

About forty-six years ago I first began to attend the meetings of the British Association; and I was elected one of your general secretaries about twenty-five years ago.

It is not unfitting, therefore, that I should recall to your minds the conditions under which science was pursued at the formation of the Association, as well as the very remarkable position which the Association has occupied in relation to science in this country.

Between the end of the sixteenth century and the early part of the present century several societies had been created to develop various branches of science. Some of these societies were established in London, and others in important provincial centres.

In 1831, in the absence of railways, communication between different parts of the country was slow and difficult. Science was therefore localised; and in addition to the universities in England, Scotland, and Ireland, the towns of Birmingham, Manchester, Plymouth and York each maintained an important nucleus of scientific research.

ORIGIN OF THE BRITISH ASSOCIATION.

Under these social conditions the British Association was founded in September 1831.

The general idea of its formation was derived from a migratory society which had been previously formed in Germany; but whilst the German society met for the special occasion on which it was summoned, and then dissolved, the basis of the British Association was continuity.

The objects of the founders of the British Association were enunciated in their earliest rules to be:—

"To give a stronger impulse and a more systematic direction to scientific inquiry; to promote the intercourse of those who cultivated science in different parts of the British Empire with one another, and with foreign philosophers; to obtain a more general attention to the objects of science, and a removal of any disadvantages of a public kind which impede its progress."

Thus the British Association for the Advancement of Science based its utility upon the opportunity it afforded for combination.

The first meeting of the Association was held at York with 353 members.

As an evidence of the want which the Association supplied, it may be mentioned that at the second meeting, which was held at Oxford, the number of members was 435. The third meeting, at Cambridge, numbered over 900 members, and at the meeting at Edinburgh in 1834 there were present 1298 members.

At its third meeting, which was held at Cambridge in 1833, the Association, through the influence it had already acquired, induced the Government to grant a sum of £500 for the reduction of the astronomical observations of Baily. And at the same meeting the General Committee commenced to appropriate to grants to research the surplus from the subscriptions of its members. The committees on each branch of science were desired "to select definite and important objects of science, which they may think most fit to be advanced by an application of the funds of the society, either in compensation for labour, or in defraying the expense of apparatus, or otherwise, stating their reasons for their selection, and, when they may think proper, designating individuals to undertake the desired investigations."

The several proposals were submitted to the Committee of Recommendations, whose approval was necessary before they could be passed by the General Committee. The regulations then laid down still guide the Association in the distribution of its grants. At that early meeting the Association was enabled to apply £600 to these objects.

I have always wondered at the foresight of the framers of the constitution of the British Association, the most remarkable feature of which is the lightness of the tie which holds it together. It is not bound by any complex central organisation. It consists of a federation of Sections, whose youth and energy are yearly renewed by a succession of presidents and vice-presidents, whilst in each Section some continuity of action is secured by the less movable secretaries.

The governing body is the General Committee, the members of which are selected for their scientific work; but their controlling power is tempered by the law that all changes of rules, or of constitution, should be submitted to, and receive the approval of, the Committee of Recommendations. This committee may be described as an ideal Second Chamber. It consists of the most experienced members of the Association.

The administration of the Association in the interval between annual meetings is carried on by the Council, an executive body, whose duty it is to complete the work of the annual meeting (*a*) by the publication of its proceedings; (*b*) by giving effect to resolutions passed by the General Committee; (*c*) it also appoints the Local Committee and organises the *personnel* of each Section for the next meeting.

I believe that one of the secrets of the long-continued success and vitality of the British Association lies in this purely democratic constitution, combined with the compulsory careful consideration which must be given to suggested organic changes.

The Association is now in the sixty-fifth year of its existence. In its origin it invited the philosophical societies dispersed throughout Great Britain to unite in a co-operative union.

Within recent years it has endeavoured to consolidate that union.

At the present time almost all important local scientific societies scattered throughout the country, some sixty-six in number, are in correspondence with the Association. Their delegates hold annual conferences at our meetings. The Association has thus extended the sphere of its action: it places the members of the local societies engaged in scientific work in relation with each other, and brings them into co-operation with members of the Association and with others engaged in original investigations, and the papers which the individual societies publish annually are catalogued in our Report. Thus by degrees a national catalogue will be formed of the scientific work of these societies.

The Association has, moreover, shown that its scope is coterminous with the British Empire by holding one of its annual meetings at Montreal, and we are likely soon to hold a meeting in Toronto.

CONDITION OF CERTAIN SCIENCES AT THE FORMATION OF THE BRITISH ASSOCIATION.

The Association, at its first meeting, began its work by initiating a series of reports upon the then condition of the several sciences.

A rapid glance at some of these reports will not only show the enormous strides which have been made since 1831 in the investigation of facts to elucidate the laws of nature, but it may afford a slight insight into the impediments offered to the progress of investigation by the mental condition of the community, which has been for so long satisfied to accept assumptions without undergoing the labour of testing their truth by ascertaining the real facts. This habit of mind may be illustrated by two instances selected from the early reports made to the Association. The first is afforded by the report made in 1832, by Mr. Lubbock, on "Tides."

This was a subject necessarily of importance to England as a dominant power at sea. But in England records of the tides had only recently been commenced at the dockyards of Woolwich, Sheerness, Portsmouth, and Plymouth, on the request of the Royal Society, and no information had been collected upon the tides on the coasts of Scotland and Ireland.

The British Association may feel pride in the fact that within three years of its inception, viz. by 1834, it had induced the Corporation of Liverpool to establish two tide gauges, and the

Government to undertake tidal observations at 500 stations on the coasts of Britain.

Another cognate instance is exemplified by a paper read at the second meeting, in 1832, upon the State of Naval Architecture in Great Britain. The author contrasts the extreme perfection of the carpentry of the internal fittings of the vessels with the remarkable deficiency of mathematical theory in the adjustment of the external form of vessels, and suggests the benefit of the application of refined analysis to the various practical problems which ought to interest shipbuilders—problems of capacity, of displacement, of stowage, of velocity, of pitching and rolling, of masting, of the effects of sails and of the resistance of fluids; and, moreover, suggests that large-scale experiments should be made by Government, to afford the necessary data for calculation.

Indeed, when we consider how completely the whole habit of mind of the populations of the Western world has been changed, since the beginning of the century, from willing acceptance of authority as a rule of life to a universal spirit of inquiry and experimental investigation, is it not probable that this rapid change has arisen from society having been stirred to its foundations by the causes and consequences of the French Revolution?

One of the earliest practical results of this awakening in France was the conviction that the basis of scientific research lay in the accuracy of the standards by which observations could be compared; and the following principles were laid down as a basis for their measurements of length, weight, and capacity: viz. (1) that the unit of linear measure applied to matter in its three forms of extension, viz. length, breadth, and thickness, should be the standard of measures of length, surface, and solidity; (2) that the cubic contents of the linear measure in decimetres of pure water at the temperature of its greatest density should furnish at once the standard weight and the measure of capacity.[1] The metric system did not come into full operation in France till 1840; and it is now adopted by all countries on the continent of Europe except Russia.

The standards of length which were accessible in Great Britain at the formation of the Association were the Parliamentary standard yard lodged in the Houses of Parliament (which was destroyed in 1834 in the fire which burned the Houses of Parliament); the Royal Astronomical Society's standard; and the 10-foot bar of the Ordnance Survey.

The first two were assumed to afford exact measurements at a given temperature. The Ordnance bar was formed of two bars on the principle of a compensating pendulum, and afforded measurements independent of temperature. Standard bars were also disseminated throughout the country, n possession of the corporations of various towns.

The British Association early recognised the importance of uniformity in the record of scientific facts, as well as the necessity for an easy method of comparing standards and for verifying differences between instruments and apparatus required by various observers pursuing similar lines of investigation. At its meeting at Edinburgh in 1834 it caused a comparison to be made between the standard bar at Aberdeen, constructed by Troughton, and the standard of the Royal Astronomical Society, and reported that the scale "was exceedingly well finished; it was about $\frac{1}{500}$th of an inch shorter than the 5-feet of the Royal Astronomical Society's scale, but it was evident that a great number of minute, yet important, circumstances have hitherto been neglected in the formation of such scales, without an attention to which they cannot be expected to accord with that degree of accuracy which the present state of science demands." Subsequently, at the meeting at Newcastle in 1863, the Association appointed a committee to report on the best means of providing for a uniformity of weights and measures with reference to the interests of science. This committee recommended the metric decimal system a recommendation which has been endorsed by a committee of the House of Commons in the last session of last Parliament.

British instrument-makers had been long conspicuous for accuracy of workmanship. Indeed, in the eighteenth century practical astronomy had been mainly in the hands of British observers; for although the mathematicians of France and other countries on the continent of Europe were occupying the foremost place in mathematical investigation, means of astronomical observation had been furnished almost exclusively by English artisans.

[1] The litre is the volume of a kilogramme of pure water at its maximum density, and is slightly less than the litre was intended to be, viz. one cubic decimetre. The weight of a cubic decimetre of pure water is 1·000013 kilogrammes.

The sectors, quadrants, and circles of Ramsden, Bird, and Cary were inimitable by continental workmen.

But the accuracy of the mathematical-instrument maker had not penetrated into the engineer's workshop. And the foundation of the British Association was coincident with a rapid development of mechanical appliances.

At that time a good workman had done well if the shaft he was turning, or the cylinder he was boring, "was right to the $\frac{1}{32}$nd of an inch." This was, in fact, a degree of accuracy as fine as the eye could usually distinguish.

Few mechanics had any distinct knowledge of the method to be pursued for obtaining accuracy; nor, indeed, had practical men sufficiently appreciated either the immense importance or the comparative facility of its acquisition.

The accuracy of workmanship essential to this development of mechanical progress required very precise measurements of length, to which reference could be easily made. No such standards were then available for the workshops. But a little before 1830 a young workman named Joseph Whitworth realised that the basis of accuracy in machinery was the making of a true plane. The idea occurred to him that this could only be secured by making three independent plane surfaces: if each of these would lift the other, they must be planes, and they must be true.

The true plane rendered possible a degree of accuracy beyond the wildest dreams of his contemporaries in the construction of the lathe and the planing machine, which are used in the manufacture of all tools.

His next step was to introduce an exact system of measurement, generally applicable in the workshop.

Whitworth felt that the eye was altogether inadequate to secure this, and appealed to the sense of touch for affording a means of comparison. If two plugs be made to fit into a round hole, they may differ in size by a quantity imperceptible to the eye, or to any ordinary process of measurement, but in fitting them into the hole the difference between the larger and the smaller is felt immediately by the greater ease with which the smaller one fits. In this way a child can tell which is the larger of two cylinders differing in thickness by no more than $\frac{1}{5000}$th of an inch.

Standard gauges, consisting of hollow cylinders with plugs to fit, but differing in diameter by the $\frac{1}{1000}$th or the $\frac{1}{10000}$th of an inch, were given to his workmen, with the result that a degree of accuracy inconceivable to the ordinary mind became the rule of the shop.

To render the construction of accurate gauges possible, Whitworth devised his measuring machine, in which the movement was effected by a screw; by this means the distance between two true planes might be measured to the one-millionth of an inch.

These advances in precision of measurement have enabled the degree of accuracy which was formerly limited to the mathematical-instrument maker to become the common property of every machine shop. And not only is the latest form of steam-engine, in the accuracy of its workmanship, little behind the chronometer of the early part of the century, but the accuracy in the construction of experimental apparatus which has thus been introduced has rendered possible recent advances in many lines of research.

Lord Kelvin said, in his Presidential Address at Edinburgh, "Nearly all the grandest discoveries of science have been but the rewards of accurate measurement and patient, long-continued labour in the sifting of numerical results." The discovery of argon, for which Lord Rayleigh and Prof. Ramsay have been awarded the Hodgkin prize by the Smithsonian Institution, affords a pregnant illustration of the truth of this remark. Indeed, the provision of accurate standards not only of length, but of weight, capacity, temperature, force, and energy, are amongst the foundations of scientific investigation.

In 1842, the British Association obtained the opportunity of extending its usefulness in this direction.

In that year the Government gave up the Royal Observatory at Kew, and offered it to the Royal Society, who declined it. But the British Association accepted the charge. Their first object was to continue Sabine's valuable observations upon the vibrations of a pendulum in various gases, and to promote pendulum observations in different parts of the world. They subsequently extended it into an observatory for comparing and verifying the various instruments which recent discoveries in physical science had suggested for continuous meteorological and magnetic observations, for observations and experiments on atmospheric electricity, and for the study of solar physics.

This new departure afforded a means for ascertaining the advantages and disadvantages of the several varieties of scientific instruments; as well as for standardising and testing instruments, not only for instrument-makers, but especially for observers by whom simultaneous observations were then being carried on in different parts of the world; and also for training observers proceeding abroad on scientific expeditions.

Its special object was to promote original research, and expenditure was not to be incurred on apparatus merely intended to exhibit the necessary consequences of known laws.

The rapid strides in electrical science had attracted attention to the measurement of electrical resistances, and in 1859 the British Association appointed a special committee to devise a standard. The standard of resistance proposed by that committee became the generally accepted standard, until the requirements of that advancing science led to the adoption of an international standard.

In 1866 the Meteorological Department of the Board of Trade entered into close relations with the Kew Observatory.

And in 1871 Mr. Gassiot transferred £10,000 upon trust to the Royal Society for the maintenance of the Kew Observatory, for the purpose of assisting in carrying on magnetical, meteorological, and other physical observations. The British Association thereupon, after having maintained this Observatory for nearly thirty years, at a total expenditure of about £12,000, handed the Observatory over to the Royal Society.

The *Transactions* of the British Association are a catalogue of its efforts in every branch of science, both to promote experimental research and to facilitate the application of the results to the practical uses of life.

But probably the marvellous development in science which has accompanied the life-history of the Association will be best appreciated by a brief allusion to the condition of some of the branches of science in 1831 as compared with their present state.

GEOLOGICAL AND GEOGRAPHICAL SCIENCE.

Geology.

At the foundation of the Association geology was assuming a prominent position in science. The main features of English geology had been illustrated as far back as 1821, and, among the founders of the British Association, Murchison and Phillips, Buckland, Sedgwick and Conybeare, Lyell and De la Beche, were occupied in investigating the data necessary for perfecting a geological chronology by the detailed observations of the various British deposits, and by their co-relation with the continental strata. They were thus preparing the way for those large generalisations which have raised geology to the rank of an inductive science.

In 1831 the Ordnance maps published for the southern counties had enabled the Government to recognise the importance of a geological survey by the appointment of Mr. De la Beche to affix geological colours to the maps of Devonshire and portions of Somerset, Dorset and Cornwall; and in 1835, Lyell, Buckland and Sedgwick induced the Government to establish the Geological Survey Department, not only for promoting geological science, but on account of its practical bearing on agriculture, mining, the making of roads, railways, and canals, and on other branches of national industry.

Geography.

The Ordnance Survey appears to have had its origin in a proposal of the French Government to make a joint measurement of an arc of the meridian. This proposal fell through at the outbreak of the Revolution; but the measurement of the base for that object was taken as a foundation for a national survey. In 1831, however, the Ordnance Survey had only published the 1-inch map for the southern portion of England, and the great triangulation of the kingdom was still incomplete.

In 1834 the British Association urged upon the Government that the advancement of various branches of science was greatly retarded by the want of an accurate map of the whole of the British Isles; and that, consequently, the engineer and meteorologist, the agriculturist and the geologist, were each fettered in their scientific investigations by the absence of those accurate data which now lie ready to his hand for the measurement of length, of surface, and of altitude.

Yet the first decade of the British Association was coincident with a considerable development of geographical research. The Association was persistent in pressing on the Government the scientific importance of sending the expedition of Ross to the Antarctic and of Franklin to the Arctic regions. We may trust that we are approaching a solution of the geography of the North Pole; but the Antarctic regions still present a field for the researches of the meteorologist, the geologist, the biologist, and the magnetic observer, which the recent voyage of M. Borchgrevink leads us to hope may not long remain unexplored.

In the same decade the question of an alternative route to India by means of a communication between the Mediterranean and the Persian Gulf was also receiving attention, and in 1835 the Government employed Colonel Chesney to make a survey of the Euphrates valley in order to ascertain whether that river would enable a practicable route to be formed from Iskanderoon, or Tripoli, opposite Cyprus, to the Persian Gulf. His valuable surveys are not, however, on a sufficiently extensive scale to enable an opinion to be formed as to whether a navigable waterway through Asia Minor is physically practicable, or whether the cost of establishing it might not be prohibitive.

The advances of Russia in Central Asia have made it imperative to provide an easy, rapid, and alternative line of communication with our Eastern possessions, so as not to be dependent upon the Suez Canal in time of war. If a navigation cannot be established, a railway between the Mediterranean and the Persian Gulf has been shown by the recent investigations of Messrs. Hawkshaw and Hayter, following on those of others, to be perfectly practicable and easy of accomplishment; such an undertaking would not only be of strategical value, but it is believed it would be commercially remunerative.

Speke and Grant brought before the Association, at its meeting at Newcastle in 1863, their solution of the mystery of the Nile basin, which had puzzled geographers from the days of Herodotus; and the efforts of Livingstone and Stanley and others have opened out to us the interior of Africa. I cannot refrain here from expressing the deep regret which geologists and geographers, and indeed all who are interested in the progress of discovery, feel at the recent death of Joseph Thomson. His extensive, accurate, and trustworthy observations added much to our knowledge of Africa, and by his premature death we have lost one of its most competent explorers.

CHEMICAL, ASTRONOMICAL AND PHYSICAL SCIENCE.

Chemistry.

The report made to the Association on the state of the chemical sciences in 1832, says that the efforts of investigators were then being directed to determining with accuracy the true nature of the substances which compose the various products of the organic and inorganic kingdoms, and the exact ratios by weight which the different constituents of these substances bear to each other.

But since that day the science of chemistry has far extended its boundaries. The barrier has vanished which was supposed to separate the products of living organisms from the substances of which minerals consist, or which could be formed in the laboratory. The number of distinct carbon compounds obtainable from organisms has greatly increased; but it is small when compared with the number of such compounds which have been artificially formed. The methods of analysis have been perfected. The physical, and especially the optical, properties of the various forms of matter have been closely studied, and many fruitful generalisations have been made. The form in which these generalisations would now be stated may probably change, some, perhaps, by the overthrow or disuse of an ingenious guess at nature's workings, but more by that change which is the ordinary growth of science—namely, inclusion in some simpler and more general view.

In these advances the chemist has called the spectroscope to his aid. Indeed, the existence of the British Association has been practically coterminous with the comparatively newly developed science of spectrum analysis, for though Newton,[1] Wollaston, Fraunhofer, and Fox Talbot had worked at the subject long ago, it was not till Kirchhoff and Bunsen set a seal on the prior labours of Stokes, Angstrom, and Balfour Stewart that the spectra of terrestrial elements have been mapped out and grouped; that by its help new elements have been discovered,

[1] Joannes Marcus Marci, of Kronland in Bohemia, was the only predecessor of Newton who had any knowledge of the formation of a spectrum by a prism. He not only observed that the coloured rays diverged as they left the prism, but that a coloured ray did not change in colour after transmission through a prism. His book, *Thaumantias, liber de arcu cœlesti deque colorum apparentium natura*, Prag. 1648, was, however, not known to Newton, and had no influence upon future discoveries.

and that the idea has been suggested that the various orders of spectra of the same element are due to the existence of the element in different molecular forms—allotropic or otherwise—at different temperatures.

But great as have been the advances of terrestrial chemistry through its assistance, the most stupendous advance which we owe to the spectroscope lies in the celestial direction.

Astronomy.

In the earlier part of this century, whilst the sidereal universe was accessible to investigators, many problems outside the solar system seemed to be unapproachable.

At the third meeting of the Association, at Cambridge, in 1833, Dr. Whewell said that astronomy is not only the queen of science, but the only perfect science. which was "in so elevated a state of flourishing maturity that all that remained was to determine with the extreme of accuracy the consequences of its rules by the profoundest combinations of mathematics; the magnitude of its data by the minutest scrupulousness of observation."

But in the previous year, viz. 1832, Airy, in his report to the Association on the progress of astronomy, had pointed out that the observations of the planet Uranus could not be united in one elliptic orbit; a remark which turned the attention of Adams to the discovery of Neptune. In his report on the position of optical science in 1832, Brewster suggested that with the assistance of adequate instruments "it would be possible to study the action of the elements of material bodies upon rays of artificial light, and thereby to discover the analogies between their affinities and those which produce the fixed lines in the spectra of the stars; and thus to study the effects of the combustions which light up the suns of other systems."

This idea has now been realised. All the stars which shine brightly enough to impress an image of the spectrum upon a photographic plate have been classified on a chemical basis. The close connection between stars and nebulæ has been demonstrated; and while on the one hand the modern science of thermodynamics has shown that the hypothesis of Kant and Laplace on stellar formation is no longer tenable, inquiry has indicated that the true explanation of stellar evolution is to be found in the gradual condensation of meteoritic particles, thus justifying the suggestions put forward long ago by Lord Kelvin and Prof. Tait.

We now know that the spectra of many of the terrestrial elements in the chromosphere of the sun differ from those familiar to us in our laboratories. We begin to glean the fact that the chromospheric spectra are similar to those indicated by the absorption going on in the hottest stars, and Lockyer has not hesitated to affirm that these facts would indicate that in those localities we are in the presence of the actions of temperatures sufficiently high to break up our chemical elements into finer forms. Other students of these phenomena may not agree in this view, and possibly the discrepancies may be due to default in our terrestrial chemistry. Still, I would recall to you that Dr. Carpenter, in his Presidential Address at Brighton in 1872, almost censured the speculations of Frankland and Lockyer in 1868 for attributing a certain bright line in the spectrum of solar prominences (which was not identifiable with that of any known terrestrial source of light) to a hypothetical new substance which they proposed to call "helium," because "it had not received that verification which, in the case of Crookes' search for thallium, was afforded by the actual discovery of the new metal." Ramsay has now shown that this gas is present in dense minerals on earth; but we have now also learned from Lockyer that it and other associated gases are not only found with hydrogen in the solar chromosphere, but that these gases, with hydrogen, form a large percentage of the atmospheric constituents of some of the hottest stars in the heavens.

The spectroscope has also made us acquainted with the motions and even the velocities of those distant orbs which make up the sidereal universe. It has enabled us to determine that many stars, single to the eye, are really double, and many of the conditions of these strange systems have been revealed. The rate at which matter is moving in solar cyclones and winds is now familiar to us. And I may also add that quite recently this wonderful instrument has enabled Prof. Keeler to verify Clerk Maxwell's theory that the rings of Saturn consist of a marvellous company of separate moons—as it were, a cohort of courtiers revolving round their queen—with velocities proportioned to their distances from the planet.

Physics.

If we turn to the sciences which are included under physics, the progress has been equally marked.

In optical science, in 1831, the theory of emission as contrasted with the undulatory theory of light was still under discussion.

Young, who was the first to explain the phenomena due to the interference of the rays of light as a consequence of the theory of waves, and Fresnel, who showed the intensity of light for any relative position of the interference-waves, both had only recently passed away.

The investigations into the laws which regulate the conduction and radiation of heat, together with the doctrine of latent and of specific heat, and the relations of vapour to air, had all tended to the conception of a material heat, or caloric, communicated by an actual flow and emission.

It was not till 1834 that improved thermometrical appliances had enabled Forbes and Melloni to establish the polarisation of heat, and thus to lay the foundation of an undulatory theory for heat similar to that which was in progress of acceptation for light.

Whewell's report, in 1832, on magnetism and electricity shows that these branches of science were looked upon as cognate, and that the theory of two opposite electric fluids was generally accepted.

In magnetism, the investigations of Hansteen, Gauss, and Weber in Europe, and the observations made under the Imperial Academy of Russia over the vast extent of that Empire, had established the existence of magnetic poles, and had shown that magnetic disturbances were simultaneous at all the stations of observation.

At their third meeting the Association urged the Government to establish magnetic and meteorological observatories in Great Britain and her colonies and dependencies in different parts of the earth, furnished with proper instruments, constructed on uniform principles, and with provisions for continued observations at those places.

In 1839 the British Association had a large share in inducing the Government to initiate the valuable series of experiments for determining the intensity, the declination, the dip, and the periodical variations of the magnetic needle which were carried on for several years, at numerous selected stations over the surface of the globe, under the directions of Sabine and Lefroy.

In England systematic and regular observations are still made at Greenwich, Kew, and Stonyhurst. For some years past similar observations by both absolute and self-recording instruments have also been made at Falmouth—close to the home of Robert Were Fox, whose name is inseparably connected with the early history of terrestrial magnetism in this country—but under such great financial difficulties that the continuance of the work is seriously jeopardised. It is to be hoped that means may be forthcoming to carry it on. Cornishmen, indeed, could found no more fitting memorial of their distinguished countryman, John Couch Adams, than by suitably endowing the magnetic observatory in which he took so lively an interest.

Far more extended observation will be needed before we can hope to have an established theory as to the magnetism of the earth. We are without magnetic observations over a large part of the southern hemisphere. And Prof. Rücker's recent investigations tell us that the earth seems as it were alive with magnetic forces, be they due to electric currents or to variations in the state of magnetised matter; that the disturbances affect not only the diurnal movement of the magnet, but that even the small part of the secular change which has been observed, and which has taken centuries to accomplish, is interfered with by some slower agency. And, what is more important, he tells us that none of these observations stand as yet upon a firm basis, because standard instruments have not been in accord; and much labour, beyond the power of individual effort, has hitherto been required to ascertain whether the relations between them are constant or variable.

In electricity, in 1831, just at the time when the British Association was founded, Faraday's splendid researches in electricity and magnetism at the Royal Institution had begun with his discovery of magneto-electric induction, his investigation of the laws of electro-chemical decomposition, and of the mode of electrolytical action.

But the practical application of our electrical knowledge was then limited to the use of lightning-conductors for buildings and ships. Indeed, it may be said that the applications of elec-

tricity to the use of man have grown up side by side with the British Association.

One of the first practical applications of Faraday's discoveries was in the deposition of metals and electro-plating, which has developed into a large branch of national industry; and the dissociating effect of the electric arc, for the reduction of ores, and in other processes, is daily obtaining a wider extension.

But probably the application of electricity which is tending to produce the greatest change in our mental, and even material condition, is the electric telegraph and its sister, the telephone. By their agency not only do we learn, almost at the time of their occurrence, the events which are happening in distant parts of the world, but they are establishing a community of thought and feeling between all the nations of the world which is influencing their attitude towards each other, and, we may hope, may tend to weld them more and more into one family.

The electric telegraph was introduced experimentally in Germany in 1833, two years after the formation of the Association. It was made a commercial success by Cooke and Wheatstone in England, whose first attempts at telegraphy were made on the line from Euston to Camden Town in 1837, and on the line from Paddington to West Drayton in 1838.

The submarine telegraph to America, conceived in 1856, became a practical reality in 1861 through the commercial energy of Cyrus Field and Pender, aided by the mechanical skill of Latimer Clark, Gooch, and others, and the scientific genius of Lord Kelvin. The knowledge of electricity gained by means of its application to the telegraph largely assisted the extension of its utility in other directions.

The electric light gives, in its incandescent form, a very perfect hygienic light. Where rivers are at hand the electrical transmission of power will drive railway trains and factories economically, and might enable each artisan to convert his room into a workshop, and thus assist in restoring to the labouring man some of the individuality which the factory has tended to destroy.

In 1843 Joule described his experiments for determining the mechanical equivalent of heat. But it was not until the meeting at Oxford, in 1847, that he fully developed the law of the conservation of energy, which, in conjunction with Newton's law of the conservation of momentum, and Dalton's law of the conservation of chemical elements, constitutes a complete mechanical foundation for physical science.

Who, at the foundation of the Association, would have believed some far-seeing philosopher if he had foretold that the spectroscope would analyse the constituents of the sun and measure the motions of the stars; that we should liquefy air and utilise temperatures approaching to the absolute zero for experimental research; that, like the magician in the "Arabian Nights," we should annihilate distance by means of the electric telegraph and the telephone; that we should illuminate our largest buildings instantaneously, with the clearness of day, by means of the electric current; that by the electric transmission of power we should be able to utilise the Falls of Niagara to work factories at distant places; that we should extract metals from the crust of the earth by the same electrical agency to which, in some cases, their deposition has been attributed?

These discoveries and their applications have been brought to their present condition by the researches of a long line of scientific explorers, such as Dalton, Joule, Maxwell, Helmholtz, Herz, Kelvin, and Rayleigh, aided by vast strides made in mechanical skill. But what will our successors be discussing sixty years hence? How little do we yet know of the vibrations which [illegible] light and heat! Far as we have advanced in the application of electricity to the uses of life, we know but little even yet of its real nature. We are only on the threshold of the knowledge of molecular action, or of the constitution of the all-pervading ether. Newton, at the end of the seventeenth century, in his preface to the "Principia," says: "I have [illegible] the motion of the planets by mathematical reasoning from [illegible]; and I would that we could derive the other phenomena of nature from mechanical principles by the same mode of [illegible]. For many things move me, so that I somewhat [illegible] may depend on certain forces by which the [illegible], through causes not yet known, are either [illegible] according to regular figures, or are [illegible] from each other; and these forces being [illegible], philosophers have hitherto made their attempts on [illegible] in vain."

In 1848 Faraday [illegible]: "How rapidly the knowledge of molecular forces grows upon us, and how strikingly every investigation tends to develop more and more their importance!

"A few years ago magnetism was an occult force, affecting only a few bodies; now it is found to influence all bodies, and to possess the most intimate relation with electricity, heat, chemical action, light, crystallisation; and through it the forces concerned in cohesion. We may feel encouraged to continuous labours, hoping to bring it into a bond of union with gravity itself."

But it is only within the last few years that we have begun to realise that electricity is closely connected with the vibrations which cause heat and light, and which seem to pervade all space—vibrations which may be termed the voice of the Creator calling to each atom and to each cell of protoplasm to fall into its ordained position, each, as it were, a musical note in the harmonious symphony which we call the universe.

Meteorology.

At the first meeting, in 1831, Prof. James D. Forbes was requested to draw up a report on the State of Meteorological Science, on the ground that this science is more in want than any other of that systematic direction which it is one great object of the Association to give.

Prof. Forbes made his first report in 1832, and a subsequent report in 1840. The systematic records now kept in various parts of the world of barometric pressure, of solar heat, of the temperature and physical conditions of the atmosphere at various altitudes, of the heat of the ground at various depths, of the rainfall, of the prevalence of winds, and the gradual elucidation not only of the laws which regulate the movements of cyclones and storms, but of the influences which are exercised by the sun and by electricity and magnetism, not only upon atmospheric conditions, but upon health and vitality, are gradually approximating meteorology to the position of an exact science.

England took the lead in rainfall observations. Mr. G. J. Symons organised the British Rainfall System in 1860 with 178 observers, a system which until 1876 received the help of the British Association. Now Mr. Symons himself conducts it, assisted by more than 3000 observers, and these volunteers not only make the observations, but defray the expense of their reduction and publication. In foreign countries this work is done by Government officers at the public cost.

At the present time a very large number of rain gauges are in daily use throughout the world. The British Islands have more than 3000, and India and the United States have nearly as many; France and Germany are not far behind; Australia probably has more—indeed, one colony alone, New South Wales, has more than 1100.

The storm warnings now issued under the excellent systematic organisation of the Meteorological Committee may be said to have had their origin in the terrible storm which broke over the Black Sea during the Crimean War, on November 27, 1855. Leverrier traced the progress of that storm, and seeing how its path could have been reported in advance by the electric telegraph, he proposed to establish observing stations which should report to the coasts the probability of the occurrence of a storm. Leverrier communicated with Airy, and the Government authorised Admiral FitzRoy to make tentative arrangements in this country. The idea was also adopted on the continent, and now there are few civilised countries north or south of the equator without a system of storm warning.[1]

Biological Science.

Botany.

The earliest Reports of the Association which bear on the biological sciences were those relating to botany.

In 1831 the controversy was yet unsettled between the advantages of the Linnean, or Artificial system, as contrasted with the Natural system of classification. Histology, morphology, and physiological botany, even if born, were in their early infancy.

Our records show that von Mohl noted cell division in 1835, the presence of chlorophyll corpuscles in 1837; and he first described protoplasm in 1846.

[1] It has often been supposed that Leverrier was also the first to issue a daily weather map, but that was not the case, for in the Great Exhibition of [illegible] the Electric Telegraph Company sold daily weather maps, copies of which are still in existence, and the data for them were, it is believed, obtained by Mr. James Glaisher, F.R.S., at that time Superintendent of the Meteorological Department at Greenwich.

Vast as have been the advances of physiological botany since that time, much of its fundamental principles remain to be worked out, and I trust that the establishment, for the first time, of a permanent Section for botany at the present meeting will lead the Association to take a more prominent part than it has hitherto done in the further development of this branch of biological science.

Animal Physiology.

In 1831 Cuvier, who during the previous generation had, by the collation of facts followed by careful inductive reasoning, established the plan on which each animal is constructed, was approaching the termination of his long and useful life. He died in 1832; but in 1831 Richard Owen was just commencing his anatomical investigations and his brilliant contributions to palæontology.

The impulse which their labours gave to biological science was reflected in numerous reports and communications, by Owen and others, throughout the early decades of the British Association, until Darwin propounded a theory of evolution which commanded the general assent of the scientific world. For this theory was not absolutely new. But just as Cuvier had shown that each bone in the fabric of an animal affords a clue to the shape and structure of the animal, so Darwin brought harmony into scattered facts, and led us to perceive that the moulding hand of the Creator may have evolved the complicated structures of the organic world from one or more primeval cells.

Richard Owen did not accept Darwin's theory of evolution, and a large section of the public contested it. I well remember the storm it produced—a storm of praise by my geological colleagues, who accepted the result of investigated facts; a storm of indignation such as that which would have burned Galileo at the stake from those who were not yet prepared to question the old authorities; but they diminish daily.

We are, however, as yet only on the threshold of the doctrine of evolution. Does not each investigation, even into the embryonic stage of the simpler forms of life, suggest fresh problems?

Anthropology.

The impulse given by Darwin has been fruitful in leading others to consider whether the same principle of evolution may not have governed the moral as well as the material progress of the human race. Mr. Kidd tells us that nature as interpreted by the struggle for life contains no sanction for the moral progress of the individual, and points out that if each of us were allowed by the conditions of life to follow his own inclination the average of each generation would distinctly deteriorate from that of the preceding one; but because the law of life is ceaseless and inevitable struggle and competition, ceaseless and inevitable selection and rejection, the result is necessarily ceaseless and inevitable progress. Evolution, as Sir William Flower said, is the message which biology has sent to help us on with some of the problems of human life, and Francis Galton urges that man, the foremost outcome of the awful mystery of evolution, should realise that he has the power of shaping the course of future humanity by using his intelligence to discover and expedite the changes which are necessary to adapt circumstances to man, and man to circumstances.

In considering the evolution of the human race, the science of preventive medicine may afford us some indication of the direction in which to seek for social improvement. One of the early steps towards establishing that science upon a secure basis was taken in 1835 by the British Association, who urged upon the Government the necessity of establishing registers of mortality showing the causes of death "on one uniform plan in all parts of the King's dominions, as the only means by which general laws touching the influence of causes of disease and death could be satisfactorily deduced." The general registration of births and deaths was commenced in 1838. But a mere record of death and its proximate cause is insufficient. Preventive medicine requires a knowledge of the details of the previous conditions of life and of occupation. Moreover, death is not our only or most dangerous enemy, and the main object of preventive medicine is to ward off disease. Disease of body lowers our useful energy. Disease of body or of mind may stamp its curse on succeeding generations.

The anthropometric laboratory affords to the student of anthropology a means of analysing the causes of weakness, not only in bodily, but also in mental life.

Mental actions are indicated by movements and their results. Such signs are capable of record, and modern physiology has shown that bodily movements correspond to action in nerve-centres, as surely as the motions of the telegraph-indicator express the movements of the operator's hands in the distant office.

Thus there is a relation between a defective status in brain power and defects in the proportioning of the body. Defects in physiognomical details, too finely graded to be measured with instruments, may be appreciated with accuracy by the senses of the observer; and the records show that these defects are, in a large degree, associated with a brain status lower than the average in mental power.

A report presented by one of your committees gives the results of observations made on 100,000 school-children examined individually in order to determine their mental and physical condition for the purpose of classification. This shows that about 16 per 1000 of the elementary school population appear to be so far defective in their bodily or brain condition as to need special training to enable them to undertake the duties of life, and to keep them from pauperism or crime.

Many of our feeble-minded children, and much disease and vice, are the outcome of inherited proclivities. Francis Galton has shown us that types of criminals which have been bred true to their kind are one of the saddest disfigurements of modern civilisation; and he says that few deserve better of their country than those who determine to lead celibate lives through a reasonable conviction that their issue would probably be less fitted than the generality to play their part as citizens.

These considerations point to the importance of preventing those suffering from transmissible disease, or the criminal, or the lunatic, from adding fresh sufferers to the teeming misery in our large towns. And in any case, knowing as we do the influence of environment on the development of individuals, they point to the necessity of removing those who are born with feeble minds, or under conditions of moral danger, from surrounding deteriorating influences.

These are problems which materially affect the progress of the human race, and we may feel sure that, as we gradually approach their solution, we shall more certainly realise that the theory of evolution, which the genius of Darwin impressed on this century, is but the first step on a biological ladder which may possibly eventually lead us to understand how in the drama of creation man has been evolved as the highest work of the Creator.

Bacteriology.

The sciences of medicine and surgery were largely represented in the earlier meetings of the Association, before the creation of the British Medical Association afforded a field for their more intimate discussion. The close connection between the different branches of science is causing a revival in our proceedings of discussions on some of the highest medical problems, especially those relating to the spread of infectious and epidemic disease.

It is interesting to contrast the opinion prevalent at the foundation of the Association with the present position of the question.

A report to the Association in 1834, by Prof. Henry, on contagion, says:—

"The notion that contagious emanations are at all connected with the diffusion of animalculæ through the atmosphere is at variance with all that is known of the diffusion of volatile contagion."

Whilst it had long been known that filthy conditions in air, earth and water fostered fever, cholera, and many other forms of disease, and that the disease ceased to spread on the removal of these conditions, yet the reason for their propagation or diminution remained under a veil.

Leeuwenhoek in 1680 described the yeast-cells, but Schwann in 1837 first showed clearly that fermentation was due to the activity of the yeast-cells; and, although vague ideas of fermentation had been current during the past century, he laid the foundation of our exact knowledge of the nature of the action of ferments, both organised and unorganised. It was not until 1860, after the prize of the Academy of Sciences had been awarded to Pasteur for his essay against the theory of spontaneous generation, that his investigations into the action of ferments[1] enabled him to show that the effects of the yeast-cell

[1] In speaking of ferments one must bear in mind that there are two classes of ferments: one, living beings, such as yeast "organised" ferments, as they are sometimes called the other the products of living beings themselves, such as pepsin, &c. "unorganised ferments. Pasteur worked with the former, very little with the latter

are indissolubly bound up with the activities of the cell as a living organism, and that certain diseases, at least, are due to the action of ferments in the living being. In 1865 he showed that the disease of silkworms, which was then undermining the silk industry in France, could be successfully combated. His further researches into anthrax, fowl cholera, swine fever, rabies, and other diseases, proved the theory that those diseases are connected in some way with the introduction of a microbe into the body of an animal; that the virulence of the poison can be diminished by cultivating the microbes in an appropriate manner; and that when the virulence has been thus diminished their inoculation will afford a protection against the disease.

Meanwhile it had often been observed in hospital practice that a patient with a simple-fractured limb was easily cured, whilst a patient with a compound fracture often died from the wound. Lister was thence led, in 1865, to adopt his antiseptic treatment, by which the wound is protected from hostile microbes.

This investigation, followed by the discovery of the existence of a multitude of micro-organisms and the recognition of some of them—such as the bacillus of tubercle and the comma bacillus of cholera—as essential factors of disease; and by the elaboration of Koch and others of methods by which the several organisms might be isolated, cultivated, and their histories studied, have gradually built up the science of bacteriology. Amongst later developments are the discovery of various so-called antitoxins, such as those of diphtheria and tetanus, and the utilisation of these for the cure of disease. Lister's treatment formed a landmark in the science of surgery, and enabled our surgeons to perform operations never before dreamed of; whilst later discoveries are tending to place the practice of medicine on a firm scientific basis. And the science of bacteriology is leading us to recur to stringent rules for the isolation of infectious disease, and to the disinfection (by superheated steam) of materials which have been in contact with the sufferer.

These microbes, whether friendly or hostile, are all capable of multiplying at an enormous rate under favourable conditions. They are found in the air, in water, in the soil; but, fortunately, the presence of one species appears to be detrimental to other species, and sunshine, or even light from the sky, is prejudicial to most of them. Our bodies, when in health, appear to be furnished with special means of resisting attack, and, so far as regards their influence in causing disease, the success of the attack of a pathogenic organism upon an individual depends, as a rule, in part at least, upon the power of resistance of the individual.

But notwithstanding our knowledge of the danger arising from a state of low health in individuals, and of the universal prevalence of these micro-organisms, how careless we are in guarding the health conditions of every-day life! We have ascertained that pathogenic organisms pervade the air. Why, therefore, do we allow our meat, our fish, our vegetables, our easily contaminated milk, to be exposed to their inroads, often in the foulest localities? We have ascertained that they pervade the water we drink, yet we allow foul water from our dwellings, our pigsties, our farmyards, to pass into ditches without previous clarification, whence it flows into our streams and pollutes our rivers. We know the conditions of occupation which foster ill-health. Why, whilst we remove outside sources of impure air, do we permit the occupation of foul and unhealthy dwellings?

The study of bacteriology has shown us that although some of these organisms may be the accompaniments of disease, yet we owe it to the operation of others that the refuse caused by the cessation of animal and vegetable life is reconverted into food for fresh generations of plants and animals.

These considerations have formed a point of meeting where the biologist, the chemist, the physicist, and the statistician unite with the sanitary engineer in the application of the science of preventive medicine.

ENGINEERING.

Sewage Purification.

The early reports to the Association show that the laws of hydrostatics, hydrodynamics, and hydraulics necessary to the supply and removal of water through pipes and conduits had long been investigated by the mathematician. But the modern sanitary engineer has been driven by the needs of an increasing population to call in the chemist and the biologist to help him to provide pure water and pure air.

The purification and the utilisation of sewage occupied the attention of the British Association as early as 1864, and between 1869 and 1876 a committee of the Association made a series of valuable reports on the subject. The direct application of sewage to land, though effective as a means of purification, entailed difficulties in thickly settled districts, owing to the extent of land required.

The chemical treatment of sewage produced an effluent harmless only after having been passed over land, or if turned into a large and rapid stream, or into a tidal estuary; and it left behind a large amount of sludge to be dealt with.

Hence it was long contended that the simplest plan in favourable localities was to turn the sewage into the sea, and that the consequent loss to the land of the manurial value in the sewage would be recouped by the increase in fish-life.

It was not till the chemist called to his aid the biologist, and came to the help of the engineer, that a scientific system of sewage purification was evolved.

Dr. Frankland many years ago suggested the intermittent filtration of sewage; and Mr. Baldwin Latham was one of the first engineers to adopt it. But the valuable experiments made in recent years by the State Board of Health in Massachusetts have more clearly explained to us how by this system we may utilise micro-organisms to convert organic impurity in sewage into food fitted for higher forms of life.

To effect this we require, in the first place, a filter about five feet thick of sand and gravel, or, indeed, of any material which affords numerous surfaces or open pores. Secondly, that after a volume of sewage has passed through the filter, an interval of time be allowed, in which the air necessary to support the life of the micro-organisms is enabled to enter the pores of the filter. Thus this system is dependent upon oxygen and time. Under such conditions the organisms necessary for purification are sure to establish themselves in the filter before it has been long in use. Temperature is a secondary consideration.

Imperfect purification can invariably be traced either to a lack of oxygen in the pores of the filter, or to the sewage passing through so quickly that there is not sufficient time for the necessary processes to take place. And the power of any material to purify either sewage or water depends almost entirely upon its ability to hold a sufficient proportion of either sewage or water in contact with a proper amount of air.

Smoke Abatement.

Whilst the sanitary engineer has done much to improve the surface conditions of our towns, to furnish clean water, and to remove our sewage, he has as yet done little to purify town air. Fog is caused by the floating particles of matter in the air becoming weighted with aqueous vapour; some particles, such as salts of ammonia or chloride of sodium, have a greater affinity for moisture than others. You will suffer from fog so long as you keep refuse stored in your towns to furnish ammonia, or so long as you allow your street surfaces to supply dust, of which much consists of powdered horse manure, or so long as you send the products of combustion into the atmosphere. Therefore, when you have adopted mechanical traction for vehicles in your towns, you may largely reduce one cause of fog. And if you diminish your black smoke, you will diminish black fogs.

In manufactories you may prevent smoke either by care in firing, by using smokeless coal, or by washing the soot out of the products of consumption in its passage along the flue leading to the main chimney-shaft.

The black smoke from your kitchen may be avoided by the use of coke or of gas. But so long as we retain the hygienic arrangement of the open fire in our living-rooms I despair of finding a fireplace, however well constructed, which will not be used in such a manner as to cause smoke, unless, indeed, the chimneys were reversed and the fumes drawn into some central shaft, where they might be washed before being passed into the atmosphere.

Electricity as a warming and cooking agent would be convenient, cleanly, and economical when generated by water power, or possibly wind power, but it is at present too dear when it has to be generated by means of coal. I can conceive, however, that our descendants may learn so to utilise electricity that they in some future century may be enabled by its means to avoid the smoke in their towns.

Mechanical Engineering.

In other branches of civil and mechanical engineering, the reports in 1831 and 1832 on the state of this science show that

the theoretical and practical knowledge of the strength of timber had obtained considerable development. But in 1830, before the introduction of railways, cast iron had been sparingly used in arched bridges for spans of from 160 to 200 feet, and wrought iron had only been applied to large-span iron bridges on the suspension principle, the most notable instance of which was the Menai Suspension Bridge, by Telford. Indeed, whilst the strength of timber had been patiently investigated by engineers, the best form for the use of iron girders and struts was only beginning to attract attention, and the earlier volumes of our *Transactions* contained numerous records of the researches of Eaton Hodgkinson, Barlow, Rennie, and others. It was not until twenty years later that Robert Stephenson and William Fairbairn erected the tubular bridge at Menai, followed by the more scientific bridge erected by Brunel at Saltash. These have now been entirely eclipsed by the skill with which the estuary of the Forth has been bridged with a span of 1700 feet by Sir John Fowler and Sir Benjamin Baker.

The development of the iron industry is due to the association of the chemist with the engineer. The introduction of the hot blast by Neilson, in 1829, in the manufacture of cast iron had effected a large saving of fuel. But the chemical conditions which affect the strength and other qualities of iron, and its combinations with carbon, silicon, phosphorus, and other substances, had at that time scarcely been investigated.

In 1856 Bessemer brought before the British Association at Cheltenham his brilliant discovery for making steel direct from the blast furnace, by which he dispensed with the laborious process of first removing the carbon from pig-iron by puddling, and then adding by cementation the required proportion of carbon to make steel. This discovery, followed by Siemens's regenerative furnace, by Whitworth's compressed steel, and by the use of alloys and by other improvements too numerous to mention here, have revolutionised the conditions under which metals are applied to engineering purposes.

Indeed, few questions are of greater interest, or possess more industrial importance, than those connected with metallic alloys. This is especially true of those alloys which contain the rarer metals; and the extraordinary effects of small quantities of chromium, nickel, tungsten and titanium on certain varieties of steel have exerted profound influence on the manufacture of projectiles and on the construction of our armoured ships.

Of late years, investigations on the properties and structure of alloys have been numerous, and among the more noteworthy researches may be mentioned those of Dewar and Fleming on the distinctive behaviour, as regards the thermo-electric powers and electrical resistance, of metals and alloys at the very low temperatures which may be obtained by the use of liquid air.

Prof. Roberts-Austen, on the other hand, has carefully studied the behaviour of alloys at very high temperatures, and by employing his delicate pyrometer has obtained photographic curves which afford additional evidence as to the existence of allotropic modifications of metals, and which have materially strengthened the view that alloys are closely analogous to saline solutions. In this connection it may be stated that the very accurate work of Heycock and Neville on the lowering of the solidifying points of molten metals, which is caused by the presence of other metals, affords a valuable contribution to our knowledge.

Prof. Roberts-Austen has, moreover, shown that the effect of any one constituent of an alloy upon the properties of the principal metal has a direct relation to the atomic volumes, and that it is consequently possible to foretell, in a great measure, the effect of any given combination.

A new branch of investigation, which deals with the microstructure of metals and alloys, is rapidly assuming much importance. It was instituted by Sorby in a communication which he made to the British Association in 1864, and its development is due to many patient workers, among whom M. Osmond occupies a prominent place.

Metallurgical science has brought aluminium into use by cheapening the process of its extraction; and if by means of the wasted forces in our rivers, or possibly of the wind, the extraction be still further cheapened by the aid of electricity, we may not only utilise the metal or its alloys in increasing the spans of our bridges, and in affording strength and lightness in the construction of our ships, but we may hope to obtain a material which may render practicable the dreams of Icarus and of Maxim, and for purposes of rapid transit enable us to navigate the air.

Long before 1831 the steam-engine had been largely used on rivers and lakes, and for short sea passages, although the first Atlantic steam-service was not established till 1838.

As early as 1820 the steam-engine had been applied by Gurney, Hancock, and others to road traction. The absurd impediments placed in their way by road trustees, which, indeed, are still enforced, checked any progress. But the question of mechanical traction on ordinary roads was practically shelved in 1830, at the time of the formation of the British Association, when the locomotive engine was combined with a tubular boiler and an iron road on the Liverpool and Manchester Railway.

Great, however, as was the advance made by the locomotive engine of Robert Stephenson, these earlier engines were only toys compared with the compound engines of to-day which are used for railways, for ships, or for the manufacture of electricity. Indeed, it may be said that the study of the laws of heat, which have led to the introduction of various forms of motive power, are gradually revolutionising all our habits of life.

The improvements in the production of iron, combined with the developed steam-engine, have completely altered the conditions of our commercial intercourse on land; whilst the changes caused by the effects of these improvements in shipbuilding, and on the ocean carrying trade, have been, if anything, still more marked.

At the foundation of the Association all ocean ships were built by hand, of wood, propelled by sails and manœuvred by manual labour; the material limited their length, which did not often exceed 100 feet, and the number of English ships of over 500 tons burden was comparatively small.

In the modern ships steam power takes the place of manual labour. It rolls the plates of which the ship is constructed, bends them to the required shape, cuts, drills, and rivets them in their place. It weighs the anchor; it propels the ship in spite of winds or currents; it steers, ventilates, and lights the ship when on the ocean. It takes the cargo on board and discharges it on arrival.

The use of iron favours the construction of ships of a large size, of forms which afford small resistance to the water, and with compartments which make the ships practically unsinkable in heavy seas, or by collision. Their size, the economy with which they are propelled, and the certainty of their arrival, cheapens the cost of transport.

The steam-engine, by compressing air, gives us control over the temperature of cool chambers. In these not only fresh meat, but the delicate produce of the Antipodes, is brought across the ocean to our doors without deterioration.

Whilst railways have done much to alter the social conditions of each individual nation, the application of iron and steam to our ships is revolutionising the international commercial conditions of the world; and it is gradually changing the course of our agriculture, as well as of our domestic life.

But great as have been the developments of science in promoting the commerce of the world, science is asserting its supremacy even to a greater extent in every department of war. And perhaps this application of science affords at a glance, better than almost any other, a convenient illustration of the assistance which the chemical, physical, and electrical sciences are affording to the engineer.

The reception of warlike stores is not now left to the uncertain judgment of "practical men," but is confided to officers who have received a special training in chemical analysis, and in the application of physical and electrical science to the tests by which the qualities of explosives, of guns, and of projectiles can be ascertained.

For instance, take explosives. Till quite recently black and brown powders alone were used, the former as old as civilisation, the latter but a small modern improvement adapted to the increased size of guns. But now the whole family of nitro-explosives are rapidly superseding the old powder. These are the direct outcome of chemical knowledge; they are not mere chance inventions, for every improvement is based on chemical theories, and not on random experiment.

The construction of guns is no longer a haphazard operation. In spite of the enormous forces to be controlled and the sudden violence of their action, the researches of the mathematician have enabled the just proportions to be determined with accuracy; the labours of the physicist have revealed the internal conditions of the materials employed, and the best means of their favourable employment. Take, for example, Longridge's coiled-wire system, in which each successive layer of which the gun is formed receives the exact proportion of tension which enables

all the layers to act in unison. The chemist has rendered it clear that even the smallest quantities of certain ingredients are of supreme importance in affecting the tenacity and trustworthiness of the materials.

The treatment of steel to adapt it to the vast range of duties it has to perform is thus the outcome of patient research. And the use of the metals—manganese, chromium, nickel, molybdenum—as alloys with iron has resulted in the production of steels possessing varied and extraordinary properties. The steel required to resist the conjugate stresses developed, lightning fashion, in a gun necessitates qualities that would not be suitable in the projectile which that gun hurls with a velocity of some 2500 feet per second against the armoured side of a ship. The armour, again, has to combine extreme superficial hardness with great toughness, and during the last few years these qualities are sought to be attained by the application of the cementation process for adding carbon to one face of the plate, and hardening that face alone by rapid refrigeration.

The introduction of quick-firing guns from ·303 (*i.e.* about one-third) of an inch to 6-inch calibre has rendered necessary the production of metal cartridge-cases of complex forms drawn cold out of solid blocks or plate of the material; this again has taxed the ingenuity of the mechanic in the device of machinery, and of the metallurgist producing a metal possessed of the necessary ductility and toughness. The cases have to stand a pressure at the moment of firing of as much as twenty-five tons to the square inch—a pressure which exceeds the ordinary elastic limits of the steel of which the gun itself is composed.

There is nothing more wonderful in practical mechanics than the closing of the breech openings of guns, for not only must they be gas-tight at these tremendous pressures, but the mechanism must be such that one man by a single continuous movement shall be able to open or close the breech of the largest gun in some ten or fifteen seconds.

The perfect knowledge of the recoil of guns has enabled the recoil of the discharge to be utilised in compressing air or springs by which guns can be raised from concealed positions in order to deliver their fire, and then made to disappear again for loading; or the same force has been used to run up the guns automatically immediately after firing, or, as in the case of the Maxim gun, to deliver in the same way a continuous stream of bullets at the rate of ten in one second.

In the manufacture of shot and shell cast iron has been almost superseded by cast and wrought steel, though the hardened Palliser projectiles still hold their place. The forged-steel projectiles are produced by methods very similar to those used in the manufacture of metal cartridge-cases, though the process is carried on at a red heat and by machines much more powerful.

In every department concerned in the production of warlike stores electricity is playing a more and more important part. It has enabled the passage of a shot to be followed from its seat in the gun to its destination.

In the gun, by means of electrical contacts arranged in the bore, a time-curve of the passage of the shot can be determined. From this the mathematician constructs the velocity-curve, and from this, again, the pressures producing the velocity are determined, and used to check the same indications obtained by other means. The velocity of the shot after it has left the gun is easily ascertained by the Boulangé apparatus.

Electricity and photography have been laid under contribution for [illegible] records of the flight of projectiles and the effects of [illegible] at the moment of their occurrence. Many of you [illegible] Mr. Vernon Boys' marvellous photographs showing [illegible] of the shot driving before it waves of air in its [illegible].

[illegible] and photography also record the properties of [illegible] or alloys as determined by curves of cooling.

[illegible] with which electrical energy can be converted [illegible] has been taken advantage of for the firing of [illegible] in their turn can, by the same agency, be laid on [illegible] of range finders placed at a distance and in [illegible] positions; while the electric light is [illegible] at night, as well as to search out [illegible].

[illegible] of the glow-lamp, the brightness of the [illegible] that the light is not due to combustion, [illegible] of Dr. [illegible] to the examination [illegible] the interior of shells, and other similar [illegible] threat of a [illegible].

INFLUENCE OF INTERCOMMUNICATION AFFORDED BY THE BRITISH ASSOCIATION ON SCIENCE PROGRESS.

The advances in engineering which have produced the steam-engine, the railway, the telegraph, as well as our engines of war, may be said to be the result of commercial enterprise rendered possible only by the advances which have taken place in the several branches of science since 1831. Having regard to the intimate relations which the several sciences bear to each other, it is abundantly clear that much of this progress could not have taken place in the past, nor could further progress take place in the future, without intercommunication between the students of different branches of science.

The founders of the British Association based its claims to utility upon the power it afforded for this intercommunication. Mr. Vernon Harcourt (the uncle of your present General Secretary), in the address he delivered in 1832, said: "How feeble is man for any purpose when he stands alone—how strong when united with other men!

"It may be true that the greatest philosophical works have been achieved in privacy, but it is no less true that these works would never have been accomplished had the authors not mingled with men of corresponding pursuits, and from the commerce of ideas often gathered germs of apparently insulated discoveries, and without such material aid would seldom have carried their investigations to a valuable conclusion."

I claim for the British Association that it has fulfilled the objects of its founders, that it has had a large share in promoting intercommunication and combination.

Our meetings have been successful because they have maintained the true principles of scientific investigation. We have been able to secure the continued presence and concurrence of the master-spirits of science. They have been willing to sacrifice their leisure, and to promote the welfare of the Association, because the meetings have afforded them the means of advancing the sciences to which they are attached.

The Association has, moreover, justified the views of its founders in promoting intercourse between the pursuers of science, both at home and abroad, in a manner which is afforded by no other agency.

The weekly and sessional reunions of the Royal Society, and the annual soirées of other scientific societies, promote this intercourse to some extent, but the British Association presents to the young student during its week of meetings easy and continuous social opportunities for making the acquaintance of leaders in science, and thereby obtaining their directing influence.

It thus encourages, in the first place, opportunities of combination, but, what is equally important, it gives at the same time material assistance to the investigators whom it thus brings together.

The reports on the state of science at the present time, as they appear in the last volume of our *Transactions*, occupy the same important position, as records of science progress, as that occupied by those reports in our earlier years. We exhibit no symptom of decay.

SCIENCE IN GERMANY FOSTERED BY THE STATE AND MUNICIPALITIES.

Our neighbours and rivals rely largely upon the guidance of the State for the promotion of both science teaching and of research. In Germany the foundations of technical and industrial training are laid in the Realschulen, and supplemented by the Higher Technical Schools. In Berlin that splendid institution, the Royal Technical High School, casts into the shade the facilities for education in the various Polytechnics which we are now establishing in London. Moreover, it assists the practical workman by a branch department, which is available to the public for testing building materials, metals, paper, oil, and other matters. The standards of all weights and measures used in trade can be purchased from or tested by the Government Department for Weights and Measures.

For developing pure scientific research and for promoting new applications of science to industrial purposes the German Government, at the instance of von Helmholtz, and aided by the munificence of Werner von Siemens, created the Physikalische Reichsanstalt at Charlottenburg.

This establishment consists of two divisions. The first is charged with pure research, and is at the present time engaged in various thermal, optical, and electrical and other physical investigations. The second branch is employed in operations of delicate standardising to assist the wants of research students—

for instance, dilatation, electrical resistances, electric and other forms of light, pressure gauges, recording instruments, thermometers, pyrometers, lenses, tuning-forks, glass, oil-testing apparatus, viscosity of glycerine, &c.

Dr. Kohlrausch succeeded Helmholtz as president, and takes charge of the first division. Prof. Hagen, the director under him, has charge of the second division. A professor is in charge of each of the several sub-departments. Under these are various subordinate posts, held by younger men, selected for previous valuable work, and usually for a limited time.

The general supervision is under a Council consisting of a president, who is a Privy Councillor, and twenty-four members, including the president and director of the Reichsanstalt; of the other members, about ten are professors or heads of physical and astronomical observatories connected with the principal universities in Germany. Three are selected from leading firms in Germany representing mechanical, optical, and electric science, and the remainder are principal scientific officials connected with the Departments of War and Marine, the Royal Observatory at Potsdam, and the Royal Commission for Weights and Measures.

This Council meets in the winter, for such time as may be necessary, for examining the research work done in the first division during the previous year, and for laying down the scheme for research for the ensuing year; as well as for suggesting any requisite improvements in the second division. As a consequence of the position which science occupies in connection with the State in continental countries, the services of those who have distinguished themselves either in the advancement or in the application of science are recognised by the award of honours; and thus the feeling for science is encouraged throughout the nation.

Assistance to Scientific Research in Great Britain.

Great Britain maintained for a long time a leading position among the nations of the world by virtue of the excellence and accuracy of its workmanship, the result of individual energy; but the progress of mechanical science has made accuracy of workmanship the common property of all nations of the world. Our records show that hitherto, in its efforts to maintain its position by the application of science and the prosecution of research, England has made marvellous advances by means of voluntary effort, illustrated by the splendid munificence of such men as Gassiot, Joseph Whitworth, James Mason, and Ludwig Mond; and, whilst the increasing field of scientific research compels us occasionally to seek for Government assistance, it would be unfortunate if by any change voluntary effort were fettered by State control.

The following are the principal voluntary agencies which help forward scientific research in this country:—The Donation Fund of the Royal Society, derived from its surplus income. The British Association has contributed £60,000 to aid research since its formation. The Royal Institution, founded in the last century, by Count Rumford, for the promotion of research, has assisted the investigations of Davy, of Young, of Faraday, of Frankland, of Tyndall, of Dewar, and of Rayleigh. The City Companies assist scientific research and foster scientific education both by direct contributions and through the City and Guilds Institute. The Commissioners of the Exhibition of 1851 devote £6000 annually to science research scholarships, to enable students who have passed through a college curriculum and have given evidence of capacity for original research to continue the prosecution of science, with a view to its advance or to its application to the industries of the country. Several scientific societies, as, for instance, the Geographical Society and the Mechanical Engineers, have promoted direct research, each in their own branch of science, out of their surplus income; and every scientific society largely assists research by the publication, not only of its own proceedings, but often of the work going on abroad in the branch of science which it represents.

The growing abundance of matter year by year increases the burden thus thrown on their finances, and the Treasury has recently granted to the Royal Society £1000 a year, to be spent in aid of the publication of scientific papers not necessarily limited to those of that Society.

The Royal Society has long felt the importance to scientific research of a catalogue of all papers and publications relating to pure and applied science, arranged systematically both as to authors' names and as to subject treated, and the Society has been engaged for some time upon a catalogue of that nature. But the daily increasing magnitude of these publications, coupled with the necessity of issuing the catalogue with adequate promptitude, and at appropriate intervals, renders it a task which could only be performed under International co-operation. The officers of the Royal Society have therefore appealed to the Government to urge Foreign Governments to send delegates to a Conference to be held next July to discuss the desirability and the scope of such a catalogue, and the possibility of preparing it.

The universities and colleges distributed over the country, besides their function of teaching, are large promoters of research, and their voluntary exertions are aided in some cases by contributions from Parliament in alleviation of their expenses.

Certain executive departments of the Government carry on research for their own purposes, which in that respect may be classed as voluntary. The Admiralty maintains the Greenwich Observatory, the Hydrographical Department, and various experimental services; and the War Office maintains its numerous scientific departments. The Treasury maintains a valuable chemical laboratory for Inland Revenue, Customs, and agricultural purposes. The Science and Art Department maintains the Royal College of Science, for the education of teachers and students from elementary schools. It allows the scientific apparatus in the national museum to be used for research purposes by the professors. The Solar Physics Committee, which has carried on numerous researches in solar physics, was appointed by and is responsible to this Department. The Department also administers the Sir Joseph Whitworth engineering research scholarships. Other scientific departments of the Government are aids to research, as, for instance, the Ordnance and the Geological Surveys, the Royal Mint, the Natural History Museum, Kew Gardens, and other lesser establishments in Scotland and Ireland; to which may be added, to some extent, the Standards Department of the Board of Trade, as well as municipal museums, which are gradually spreading over the country.

For direct assistance to voluntary effort the Treasury contributes £4000 a year to the Royal Society for the promotion of research, which is administered under a board whose members represent all branches of science. The Treasury, moreover, contributes to marine biological observatories, and in recent years has defrayed the cost of various expeditions for biological and astronomical research, which in the case of the *Challenger* expedition involved very large sums of money.

In addition to these direct aids to science, Parliament, under the Local Taxation Act, handed over to the County Councils a sum, which amounted in the year 1893 to £615,000, to be expended on technical education. In many country districts, so far as the advancement of real scientific technical progress in the nation is concerned, much of this money has been wasted for want of knowledge. And whilst it cannot be said that the Government or Parliament have been indifferent to the promotion of scientific education and research, it is a source of regret that the Government did not devote some small portion of this magnificent gift to affording an object-lesson to County Councils in the application of science to technical instruction, which would have suggested the principles which would most usefully guide them in the expenditure of this public money.

Government assistance to science has been based mainly on the principle of helping voluntary effort. The Kew Observatory was initiated as a scientific observatory by the British Association. It is now supported by the Gassiot Trust Fund, and managed by the Kew Observatory Committee of the Royal Society. Observations on magnetism, on meteorology, and the record of sun-spots, as well as experiments upon new instruments for assisting meteorological, thermometrical, and photographic purposes, are being carried on there. The Committee has also arranged for the verification of scientific measuring instruments, the rating of chronometers, the testing of lenses and of other scientific apparatus. This institution carries on to a limited extent some small portion of the class of work done in Germany by that magnificent institution, the Reichsanstalt of Charlottenburg, but its development is fettered by want of funds. British students of science are compelled to resort to Berlin and Paris when they require to compare their more delicate instruments and apparatus with recognised standards. There could scarcely be a more advantageous addition to the assistance which Government now gives to science than for it to allot a substantial annual sum to the extension of the Kew Observatory, in order to develop it on the model of the Reichsanstalt. It

might advantageously retain its connection with the Royal Society, under a Committee of Management representative of the various branches of science concerned, and of all parts of Great Britain.

CONCLUSION.

The various agencies for scientific education have produced numerous students admirably qualified to pursue research; and at the same time almost every field of industry presents openings for improvement through the development of scientific methods. For instance, agricultural operations alone offer openings for research to the biologist, the chemist, the physicist, the geologist, the engineer, which have hitherto been largely overlooked. If students do not easily find employment, it is chiefly attributable to a want of appreciation for science in the nation at large.

This want of appreciation appears to arise from the fact that those who nearly half a century ago directed the movement of national education were trained in early life in the universities, in which the value of scientific methods was not at that time fully recognised. Hence our elementary, and even our secondary and great public schools, neglected for a long time to encourage the spirit of investigation which develops originality. This defect is diminishing daily.

There is, however, a more intangible cause which may have had influence on the want of appreciation of science by the nation. The Government, which largely profits by science, aids it with money, but it has done very little to develop the national appreciation for science by recognising that its leaders are worthy of honours conferred by the State. Science is not fashionable, and science students—upon whose efforts our progress as a nation so largely depends—have not received the same measure of recognition which the State awards to services rendered by its own officials, by politicians, and by the Army and by the Navy, whose success in future wars will largely depend on the effective applications of science.

The Reports of the British Association afford a complete chronicle of the gradual growth of scientific knowledge since 1831. They show that the Association has fulfilled the objects of its founders in promoting and disseminating a knowledge of science throughout the nation.

The growing connection between the sciences places our annual meeting in the position of an arena where representatives of the different sciences have the opportunity of criticising new discoveries and testing the value of fresh proposals, and the Presidential and Sectional Addresses operate as an annual stock-taking of progress in the several branches of science represented in the Sections. Every year the field of usefulness of the Association is widening. For, whether with the geologist we seek to write the history of the crust of the earth, or with the biologist to trace out the evolution of its inhabitants, or whether with the astronomer, the chemist, and the physicist we endeavour to unravel the constitution of the sun and the planets or the genesis of the nebulæ and stars which make up the universe, on every side we find ourselves surrounded by mysteries which await solution. We are only at the beginning of work.

I have, therefore, full confidence that the future records of the British Association will chronicle a still greater progress than that already achieved, and that the British nation will maintain its leading position amongst the nations of the world, if it will energetically continue its voluntary efforts to promote research, supplemented by that additional help from the Government which ought never to be withheld when a clear case of scientific utility has been established.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. W. M. HICKS, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

In making a choice of subject for my address the difficulty is not one of finding material but of making selection. The field covered by this Section is a wide one. Investigation is active in every part of it, and is being rewarded with a continuous stream of new discoveries and with the growth of that coordination and correlation of facts which is the surest sign of real advancement in science. The ultimate aim of pure science is to be able to explain the most complicated phenomena of nature as flowing by the fewest possible laws from the simplest fundamental data. A statement of a law is either a confession of ignorance or a mnemonic convenience. It is the latter, if it is deducible by logical reasoning from other laws. It is the former when it is only discovered as a fact to be a law. While, on the one hand, the end of scientific investigation is the discovery of laws, on the other, science will have reached its highest goal when it shall have reduced ultimate laws to one or two, the necessity of which lies outside the sphere of our cognition. These ultimate laws—in the domain of physical science at least—will be the dynamical laws of the relations of matter to number, space, and time. The ultimate data will be number, matter, space, and time themselves. When these relations shall be known, all physical phenomena will be a branch of pure mathematics. We shall have done away with the necessity of the conception of potential energy, even if it may still be convenient to retain it; and—if it should be found that all phenomena are manifestations of motion of one single continuous medium—the idea of force will be banished also, and the study of dynamics replaced by the study of the equation of continuity.

Before, however, this can be attained, we must have the working drawings of the details of the mechanism we have to deal with. These details lie outside the scope of our bodily senses; we cannot see, or feel, or hear them, and this, not because they are unseeable, but because our senses are too coarse-grained to transmit impressions of them to our mind. The ordinary methods of investigation here fail us; we must proceed by a special method, and make a bridge of communication between the mechanism and our senses by means of hypotheses. By our imagination, experience, intuition we form theories; we deduce the consequences of these theories on phenomena which come within the range of our senses, and reject or modify and try again. It is a slow and laborious process. The wreckage of rejected theories is appalling; but a knowledge of what actually goes on behind what we can see or feel is surely if slowly being attained. It is the rejected theories which have been the necessary steps towards formulating others nearer the truth. It would be an extremely interesting study to consider the history of these discarded theories; to show the part they have taken in the evolution of truer conceptions, and to trace the persistence and modification of typical ideas from one stratum of theories to a later. I propose, however, to ask your attention for a short time to one of these special theories—or rather to two related theories—on the constitution of matter and of the ether. They are known as the vortex atom theory of matter, and the vortex sponge theory of the ether. The former has been before the scientific world for a quarter of a century, since its first suggestion by Lord Kelvin in 1867, the second for about half that time. In what I have to say I wish to take the position not of an advocate for or against, but simply as a prospector attempting to estimate what return is likely to be obtained by laying down plant to develop an unknown district. This is, in fact, the state of these two theories at present. Extremely little progress has been made in their mathematical development, and until this has been done more completely we cannot test them as to their powers of adequately explaining physical phenomena.

The theory of the rigid atom has been a very fruitful one, especially in explaining the properties of matter in the gaseous state; but it gives no explanation of the apparent forces which hold atoms together, and in many other respects it requires supplementing. The elastic solid ether explained much, but there are difficulties connected with it—especially in connection with reflection and refraction—which decide against it. The mathematical rotational ether of MacCullagh is admirably adapted to meet these difficulties, but he could give no physical conception of its mechanism. Maxwell and Faraday proposed a special ether for electrical and magnetic actions. Maxwell's identification of the latter with the luminiferous ether, his deduction of the velocity of propagation of light and of indices of refraction in terms of known electrical and magnetic constants, will form one of the landmarks in the history of science. This ether requires the same mathematical treatment as that of MacCullagh. Lord Kelvin's gyrostatic model of an ether is also of the MacCullagh type. Lastly, we have Lord Kelvin's labile ether, which again avoids the objections to the elastic solid ether. In MacCullagh's type of ether the energy of the medium when disturbed depends only on the twists produced in it. This ether has recently been mathematically discussed by Dr. Larmor, who has shown that it is adequate to explain all the various phenomena of light, electricity, and magnetism. To this I hope to return later. Meanwhile, it may be borne in mind that the vortex sponge ether belongs to MacCullagh's type.

Already before a formal theory of a fluid ether had been

attempted, Lord Kelvin ("Vortex Atoms," *Proc. Roy. Soc., Edin.*, vi. 94; *Phil. Mag.* (4), 34) had proposed his theory of vortex atoms. The permanence of a vortex filament with its infinite flexibility, its fundamental simplicity with its potential capacity for complexity, struck the scientific imagination as the thing which was wanted. Unfortunately the mathematical difficulties connected with the discussion of these motions, especially the reactions of one on another, have retarded the full development of the theory. Two objections in chief have been raised against it, viz. the difficulty of accounting for the densities of various kinds of matter, and the fact that in a vortex ring the velocity of translation decreases as the energy increases. There are two ways of dealing with a difficulty occurring in a general theory—one is to give up the theory, the other is to try and see if it can be modified to get over the difficulty. Such difficulties are to be welcomed as means of help in arriving at greater exactness in details. It is a mistake to submit too readily to crucial experiments. The very valid crucial objection of Stokes to MacCullagh's ether is a case in point. It drew away attention from a theory which, in the light of later developments, gives great hope of leading us to correct ideas. As Larmor has pointed out, this objection vanishes when we have intrinsic rotations in the ether itself. A special danger to guard against is the importation into one theory of ideas which have grown out of one essentially different. This remark has reference to the apparent difficulty of decrease of velocity with increased energy.

Maxwell was, I believe, the first to point out the difficulty of explaining the masses of the elements on the vortex atom hypothesis. To me it has always appeared one of the greatest stumbling-blocks to the acceptance of the theory. We have always been accustomed to regard the ether as of extreme tenuity, as of a density extremely though not infinitely smaller than that of gross matter, and we carry in our minds that Lord Kelvin has given an inferior limit of about 10^{-19}. There are two directions in which to seek a solution. The first is to cut the knot by supposing that the atoms of gross matter are composed of filaments whose rotating cores are of much greater density than the ether itself. The second is to remember that Lord Kelvin's number was obtained on the supposition of elastic solid ether, and does not necessarily apply to the vortex sponge. Unfortunately, however, for the first explanation, the mathematical discussion[1] shows that a ring cannot be stable unless the density of the fluid outside the core is equal to, or greater than, that inside. This instability also cannot be cured by supposing an additional circulation added outside the core. Unless, therefore, some modification of the theory can be made to secure stability this idea of dense fluid cores must be given up.

We seem, then, forced back to the conclusion that the density of the ether must be comparable with that of ordinary matter. The effective mass of any atom is not composed of that of its core alone, but also of that portion of the surrounding ether which is carried along with it as it moves through the medium. Thus a rigid sphere moving in a liquid behaves as if its mass were increased by half that of the displaced liquid. In the case of a vortex filament the ratio of effective to actual mass may be much larger. In this explanation the density of the matter composing an atom is the same for all, whilst their masses depend on their volumes and configurations combined. Now the configuration alters with the energy, and this would make the mass depend to some extent at least on the temperature. However repugnant this may be to current ideas, we are not entitled to deny its possibility, although such an effect must be small or it would have been detected. Such a variation, if it exists, is not to be looked for by means of the ordinary gravitation balance, but by the inertia or ballistic balance. The mass of the core itself remains, of course, constant, but the effective mass—that which we can measure by the mechanical effects which the moving vortex produces—is a much more complicated matter, and requires much fuller consideration than has been given to it.

The conditions of stability allow us to assume vacuous cores or cores of less density than the rest of the medium. If we do this, then the density of the ether itself may be greater than that of gross matter. Until, however, we meet with phenomena whose explanation requires this assumption, it would seem preferable to take the density everywhere the same. In this case the density of the ether must be rather less than the apparent density of the lightest of any of the elements, taking the apparent density to mean the effective mass of a vortex atom per its volume. This will probably be commensurable with the density of the matter in its most compressed state, and will lie between ·5 and 1—comparable, that is to say, with the density of water. Larmor,[1] from a special form of hypothesis for a magnetic field in the rotationally elastic ether, is led to assign a density of the same order of magnitude. If the density be given it is easy to calculate the intrinsic energy per c.c. in the medium. The velocity of propagation of light in a vortex sponge ether, as deduced by Lord Kelvin,[2] is ·47 times the mean square velocity of the intrinsic motion of the medium. This gives for the mean square velocity $6·3 \times 10^{10}$ cm. per second. If we follow Lord Kelvin and use for comparison the energy of radiation per c.c. near the sun, or say 1·8 erg per c.c., the resulting density will be 10^{-21}. The energy per c.c. in a magnetic field of 15,000 c.g.s. units is about 1 joule. If we take this for comparison we get a density of 10^{-14}. But the intrinsic energy of the fluid must be extremely great compared with the energy it has to transmit. If it were a million times greater the density would still only amount to 10^{-8}—comparable with the density of the residual gas in our highest vacua. To account for the density of gross matter on the supposition that it is built up out of the same material as the ether leads to a density between ·5 and 1. This gives the enormous energy of 10^{14} joules per c.c. In other words, the energy contained in one cubic centimetre of the ether is sufficient to raise a kilometre cube of lead 1 metre high against its weight. Thus the difficulty in explaining the mass of ordinary matter seems to reduce itself to a difficulty in believing that the ether possesses such an enormous store of energy. It may be that there are special reasons against such a large density. Larmor refers to the large forcives which would be called into play by hydrodynamical motions. Perhaps an answer to this may be found in the remark that where all the matter is of the same density the motions are kinematically deducible from the configuration at the instant, and are independent of the density. It is only where other causes act, such, *e.g.*, as indirectly depend on the mean pressure of the fluid or where vacuous spaces occur, that the actual value of the density may modify the measurable forcives.

Ever since Prof. J. J. Thomson proved that a vortex atom theory of matter is competent to serve as a basis of a kinetic theory of gases, it has been urged by various persons as a fatal objection that the translation velocity of the atoms falls off as the temperature rises. I must confess this objection has never appealed to me. Why should not the velocity fall off? The velocity of gaseous molecules has never been directly observed, nor has it been experimentally proved that it increases with rise of temperature. We have no right to import ideas based on the kinetic theory of hard discrete atoms into the totally distinct theory of mobile atoms in continuity with the medium surrounding them. Doubtless the molecules of a gas effuse through a small orifice more quickly as the temperature rises, but it is natural to suppose that a vortex ring would do the same as its energy increases. To make the objection valid, it is necessary to show that a vortex ring passing through a small tube, comparable with its own diameter, would pass through more slowly the greater its energy. It is not, however, necessarily the case that in every vortex aggregate the velocity decreases as the energy increases. The mathematical treatment of thin vortex filaments is comparatively easy, and little attention has been paid to other cases. Let us attempt to trace the life history as to translation velocity and energy of a vortex ring. We start with the energy large; the ring now has a very large aperture, and has a very thin filament. As the energy decreases the aperture becomes smaller, the filament thicker, and the velocity of translation greater. We can trace quantitatively the whole of this part of its history until the thickness of the ring has increased to about four times the diameter of the aperture, or perhaps a little further. Then the mathematical treatment employed fails us or becomes very laborious to apply. Till eighteen months ago, this was the only portion of its history we could trace. Then Prof. M. J. M. Hill ("On a Spherical Vortex," *Phil. Trans.*, 1894) published his beautiful discovery of the existence of a spherical vortex. This consists of a spherical

[1] An error in the expression on p. 768 of "Researches in the Theory of Vortex Rings," *Phil. Trans.*, pt. ii. 1885, vitiates the conclusion there drawn. If this be corrected the result mentioned above follows. See also Basset, "Treatise on Hydrodynamics," § 338, and *Amer. Jour. Math.*

[1] "A Dynamical Theory of the Electric and Luminiferous Medium," *Phil. Trans.*, 1894, A. p. 779.

[2] "On the Propagation of Laminar Motion through a Turbulently Moving Inviscid Liquid," *Phil. Mag.*, October 1887.

mass of fluid in vortical motion and moving bodily through the surrounding fluid, precisely as it it were a rigid sphere. This enables us to catch a momentary glimpse, as it were, of our vortex ring some little time after it has passed out of our ken. The aperture has gone on contracting, the ring thickening, and altering the shape of its cross section in a manner whose exact details have not yet been calculated. At last we just catch sight of it again as the aperture closes up. We find the ring has changed into a spherical ball, with still further diminished energy and increased velocity. We then lose sight of it again, but it now lengthens out, and towards the end of its course approximates to the form of a rod moving parallel to its length through the fluid with energy and velocity which again can be approximately determined. In this part of its life the velocity of translation decreases with decrease of energy. I believe it will be found, when the theory is completely worked out, that the spherical atom is the stage where this reversal of property takes place.

Even in the ring state, however, the change of velocity with energy is very small; much smaller, I think, than is generally recognised. When the energy is increased to twenty times that of the spherical vortex, the velocity is only diminished to two-thirds its previous value. If at ordinary temperatures, say 20° C., the vortex was in the spherical shape, then at 3000° C. its velocity of translation would only have been reduced to four-fifths its value at the lower temperature, whilst the aperture of the ring would have a radius about 1·4 times that of the sphere. At 2000° C. the velocity would not differ by much more than one-twentieth from its original value. In fact, near the spherical state the alteration in velocity of translation is very slow. It is therefore possible, that if the atoms of matter be vortex aggregates, the state in which we can experimentally test our theory is just that in which the mathematical discussion fails us. Other modifications tend to diminish this change of velocity. I will refer here to three only. The first is that of hollow vortices. We must not, however, postulate vacuous atoms without any rotational core at all; for in this case we should probably lose the essential property of permanence. The question has not been fully investigated, but there can be little doubt that by diminishing the energy of a completely hollow vortex we can cause it to disappear. We can certainly create one in a perfect fluid. Secondly, J. J. Thomson has shown that if a molecule be composed of linked filaments, the energy increases as the components move further apart. In such a case an extra supply of energy goes to expanding the molecule, and less, if any, to increasing the aperture. Lastly, a modification of the atomic motion to which I shall refer later, and which seems called for to explain the magnetic rotation of the plane of polarisation of light, will also tend to lessen the change of size, and therefore change of velocity with change of energy, even if it does not reverse the property.

If we pass on to consider how a vortex atom theory lends itself to the explanation of physical and chemical properties of matter independently of what may be called ether relations, we find that we owe almost all our knowledge on this point to the work of Prof. J. J. Thomson ("A Treatise on the Motion of Vortex Rings," Macmillan, 1883), which obtained the Adams' Prize in 1882. This, however, is confined to the treatment of *thin* vortex rings, still leaving a wide field for future investigations in connection with thick rings and with vortex aggregates which produce no cyclosis in the surrounding medium. His work is an extremely suggestive one. He shows that such a theory is capable not only of explaining the gaseous laws of a so-called perfect gas, but possibly also the slight deviations therefrom. Quite as striking is his explanation of chemical combination—an explanation which flows quite naturally from the theory. A vortex filament can be linked on itself: two or more can be linked together, like helices drawn on an anchor ring; [illegible], several can be arranged together like parallel rings [illegible] threading one another. In the latter case, for such [illegible] to be permanent, the strengths of each ring [illegible] and further, not more than six can thus be [illegible] together. The linked vortices will be in permanent [illegible] of their linkedness; the other arrangement [illegible] subject to no external actions. If, however, they are disturbed by the presence of other vortices they may [illegible]. When atoms are thus combined to form a [illegible] will always be dis[illegible]; the compound will be permanent when the ratio of the average paired time to the unpaired time of any atom is large. Thomson considers every filament to be of the same strength. Then an atom consisting of two links will behave like a ring of twice the strength, one of three links, of three times the strength, and so on. On this theory chemical compounds are to be regarded as systems of rings, not linked into one another but close together, and all engaged in the operation of threading each other. The conditions for permanence are: (1) the strength of each ring must be the same, (2) the number must be less than 6. Now apply this. H and Cl have equal linkings, therefore equal strength. Consequently we can have molecules of HCl, or any combinations up to 6 atoms per molecule, although the simpler one is the most likely. O has twice the linking, therefore the strength double. Hence one of H and one of O cannot revolve in permanent connection. We require first to arrange two of H together to form one system. This system has the same strength as O, they can therefore revolve in permanent connection, and we get the water molecule. *Or* we may take two of the O atoms and one of the double H molecule, and they can form a triple system of three rings threading one another in permanent connection, and we get the molecule H_2O_2. This short example will be sufficient to indicate how the theory gives a complete account of valency.

The energy of rings thus combined is less than when free; consequently they are stable, and the act of combination sets free energy. Further, Thomson points out that for two rings to combine their sizes must be about the same when they come into proximity; consequently combination can only occur between two limits of temperature corresponding to the energies within which the radii of both kinds of rings are near an equality.

We can easily extend Thomson's reasoning to explain the combination of two elements by the presence of a third neutral substance. Call the two elements which are to combine A and B, and the neutral substance C. The radii of A and B are to be supposed too unequal to allow them to come close enough together to combine. If now at the given temperature the C atom has a radius intermediate to those of A and B, it is more nearly equal to each than they are to one another; C picks up one of A, and after a short time drops it; A will leave C with its radius brought up (say) to closer equality with it. The same thing happens with the B atoms, and they leave C with their radii brought down to closer equality with it. The result is that A and B are brought into closer equality with one another, and if this is of sufficient amount, they can combine and do so, while C remains as before and apparently inert.

Thomson's theory of chemical combination applies only to thin rings. Something analogous may hold also for thick rings, but it is clearly inapplicable to vortex aggregates similar to that of Hill's. We are not confined, however, to this particular kind of association of vortex atoms in a molecule. For instance, I have recently found (not yet published) that one of Hill's vortices can swallow up another and retain it inside in relative equilibrium. The matter requires fuller discussion, but it seems to open up another mode of chemical combination.

A most important matter which has not yet been discussed at all is the relation between the mean energy of the vortex cores, and the energy of the medium itself when the atoms are close enough to affect each other's motions (as in a gas). The fundamental ideas are quite different from those underlying the well-known kinetic theory of gases of hard atoms. Nevertheless, many of the results must be very similar, based as both are on dynamical ideas. Whether it will avoid certain difficulties of the latter, especially those connected with the ratio of the specific heats, remains to be seen. The first desideratum is the determination of the equilibrium of energy between vortices and medium, and before this is done it is useless to speculate further in this region.

A vortex atom theory of matter carries with it the necessity of a fluid ether. If such a fluid is to transmit transversal radiations, some kind of quasi-elasticity must be produced in it. This can be done by supposing it to possess energetic rotational motions whose mean velocity is zero, within a volume whose linear dimension is small compared with the wave-length of light, but whose velocity of mean square is considerable. That an ether thus constituted is capable of transmitting transverse vibrations I showed before this Section at the Aberdeen meeting of the Association ("On the Constitution of the Luminiferous Ether on the Vortex Atom Theory," *Brit. Asso. Reports*, 1885, p. 930), by considering a medium composed of closely packed discrete small vortex rings. Lord Kelvin ("On the Vortex Theory of the Luminiferous Ether," *Brit. Asso. Reports*, 1887, p. 486, also

Phil. Mag., October 1887, p. 342) at the Manchester meeting discussed the question much more thoroughly and satisfactorily, and deduced that the velocity of propagation was $\sqrt{2/3}$ times the velocity of mean square of the turbulent motion. We can make little further progress until we know something of the arrangement of the small motions which confer the quasi-rigidity. This may be completely irregular and unsteady, or arranged in some definite order of steady motions. I am inclined to the view that the latter is nearer the truth. In this case we should expect a regular structure of small cells in which the motions are all similar. By the word cell I do not mean a small vessel bounded by walls, but a portion of the fluid in which the motion is a complete system in itself. Such a theory might be called a cell theory of the ether. The simplest type, perhaps, is to suppose the medium spaced into rectangular boxes, in each of which the motion may be specified as follows: Holding the box with one set of faces horizontal the fluid streams up in the centre of the box, then turns round, flows down the sides and up the centre again. In fact, it behaves like a Hill's vortex squeezed from a spherical into a box form. Each box has thus rotational circulation complete in itself. The six adjoining compartments have their motion the same in kind, but in the reverse direction, and so on. In this way we get continuous and energetic small motions throughout the medium, and the state is a stable one. If there is a shear, so that each cell becomes slightly rhomboidal, the rotational motions inside tend to prevent it, and thus propagate the disturbance, but the cells produce no effect on the general irrotational motion of the fluid, at least when the irrotational velocities are small compared with those of the propagation of light. In this case the rate at which the cells adjust themselves to an equilibrium position is far quicker than the rate at which this equilibrium distribution is disturbed by the gross motions. The linear dimensions of the cells must be small compared with the wave-lengths of light. They must probably be small also compared with the atoms of gross matter, which are themselves small compared with the same standard.

We may regard each cell as a dynamical system by itself, into which we pour or take away energy. This added energy will depend only on the shape into which the box is deformed. We may then, for our convenience in considering the gross motions of the medium as a whole, *i.e.* our secondary medium, regard these as interlocked systems, neglect the direct consideration of the motions inside them, but regard the energy which they absorb as a potential function for the general motion. This potential function will contain terms of two kinds, one involving the shear of the cells, and this shear will be the *same* as the rotational deformation in the secondary medium. The second will depend on alterations in the ratios of the edges of the cells (including other changes of form involving no rotations). The former will give rise to waves of transversal displacements. The second cannot be transmitted as waves, but may produce local effects. If a continuous solid be placed in such a medium, the cells will rearrange themselves so as to keep the continuity of their motions. The cells will become distorted (but without resultant shear), and a static stress will be set up. We have then to deal with the primary stuff itself, whose rotation gives a structure to the ether, and the structural ether itself. The former we may call the primary medium. The ether which can transmit transversal disturbances, and which is built up out of the first, we may call the secondary medium. Whether an atom of matter is to be considered as a vortical mass of the primary or of the secondary medium is a matter to be left open in the present state of the theory.

At the Bath meeting of this Association, I sketched out a theory of the electrical action of a fluid ether in which electrical lines of force were vortex filaments combined with an equivalent number of hollow vortices of the same vortical strength. ("A Vortex Analogue of Static Electricity," *Brit. Assoc. Rep.*, 1888, p. 577.) An electric charge on a body depended on the number of ends of filaments abutting on it, the sign being determined by the direction of rotation of the filament looked at from the body. This theory gave a complete account of electrostatic actions, both quantitatively and qualitatively, and a more speculative one as to currents and magnetism. I could only succeed in proving at that time that if the filaments were distributed according to the same laws as electric lines of force, the distribution would be one of equilibrium. Larmor ("A Dynamical Theory of the Electric and Luminiferous Medium," *Phil. Trans.*, 1894, p. 748) has recently proved that this is also the necessary distribution for any type of a rotationally elastic ether, and consequently also for this particular case. Currents along a wire were supposed to consist of the ends of filaments running along it, with disappearance of the hollow companions, the filaments producing at the same time a circulation round the wire. A magnetic field was thus to be produced by a flow of the ether, but probably with the necessary accompaniment of rotational elements in it.

This latter, however, was clearly wrong, because each kind of filament would produce a circulation in opposite directions. The correct deduction would have been to lay stress on the fact that the field is due to the motion through the stationary ether of the vortex filaments, the field being perpendicular to the filament and to its direction of motion. This motion would doubtless produce stresses in the cell-ether due to deformations of the cells, and be the proximate cause of the mechanical forces in the field. In any case, it is not difficult to show that a magnetic field cannot be due to an irrotational flow of the ether alone.[1] Such electrostatic and magnetic fields produce states of motion in the medium, but no bodily flow in it; consequently we ought not to expect an effect to be produced on the velocity of transmission of light through it.

The fundamental postulate underlying this explanation of electric action is that when two different kinds of matter are brought into contact a distribution of vortex filaments in the neighbourhood takes place, so that a larger number stretch from one to the other than in the opposite direction—the distinction between positive and negative ends being that already indicated. To see how such a distribution may be caused, let us consider each vortex atom to be composed of a vortical mass of our secondary medium or cell-structure ether. The atom is much larger than a cell, and contains practically an infinite number of them. It is a dynamical system of these cells with equilibrium of energy throughout its volume. The second atom is a dynamical system with a different equilibrium of energy. Where they come into contact there will be a certain surface rearrangement, which will show itself as a surface distribution of energy in a similar manner to that which exists between a molar collection of one kind of molecules in contact with one of another, and which shows itself in the phenomenon which we call surface tension. In the present case the effect may take place at the interface of two atomic systems in actual contact, or be a difference effect between the two interfaces of the ether and each atom when the latter are sufficiently close. The surface effect we are now considering shows itself as contact electricity.

Such a distribution of small vortex filaments, stretching from one atom to another, will tend to hold them together. We therefore get an additional cause for aggregation of atoms. This does not exclude the others already referred to. They may all act concurrently, some producing one effect, some another—one combining, perhaps, unknown primitive atoms into elements, one elements into chemical compounds, and another producing the cohesion of matter into masses.

On this theory the difference between a conductor and a dielectric is that in a dielectric the ends of the filaments cannot pass from atom to atom, possibly because the latter never come into actual contact. In a conductor, however, we are to suppose that the atomic elements can do so. When a current is flowing, a filament and its equivalent hollow stretch between two neighbouring atoms, they are pulled into contact, or their motions bring them into contact, the hollow disappears, and the rotational filament joins its two ends and sails away as a small neutral vortex ring into the surrounding medium, or returns to its function as an ether cell. The atoms being free are now pulled back to perform a similar operation for other filaments. The result is that the atoms are set into violent vibrations, causing the heating of the conductor. When, however, the metal is at absolute zero of temperature, there is no motion, the atoms are already in contact, and there is no resistance, as the observation of Dewar and Fleming tends to show. Further, as the resistance depends on the communication of motion from molecule to molecule, we should expect the electrical conduc-

[1] To prove this, consider a straight conductor moving parallel to itself and perpendicular to a uniform magnetic field. There exists a permanent potential difference between its ends. If, however, the field consists of a flow of ether, the effect is the same as if the conductor is at rest, and the direction of the magnetic field shifted through an angle. But this is the case of a conductor at rest in a field, and there is therefore no potential difference between the ends. Hence a magnetic field must consist of some structure across which the conductor cuts. A field may possibly demand a flow of the ether, but, if so, it must carry in it some structure definitely oriented at each point to the direction of flow.

tivity of a substance to march with its thermal conductivity. Again, on this theory the resistance clearly increases with increase of distance between atoms—*i.e.* with increase of temperature. On the contrary, in electrolytic conduction the same junction of filament ends is brought about, not by oscillations of molecule to molecule, but by disruption of the molecule and passage of atom to atom. In this case conduction is easier the more easily a molecule is split up, and thus resistance decreases with increase of temperature. To explain the laws of electrolysis it is only necessary to assume that the strengths of all filaments are the same. A similar hypothesis, as we have seen, lies at the basis of J. J. Thomson's explanation of chemical combination, although it is not necessarily the case that we are dealing with the same kind of filaments. It is evident that the theory easily lends itself to his views as to the mechanism of the electric discharge through gases. The *modus operandi* of the production of the mechanical forcive on a conductor carrying a current in a magnetic field and of electrodynamic induction is not clear. Probably the full explanation is to be found in the stresses produced in the ether owing to the deformation of the cells by the passage of the filaments through them. The fluid moves according to the equation of continuity without slip, and subject to the surface conditions at the conductors. This motion, however, distorts the cells, and stresses are called into play. Any theory which can explain the mechanical forcives and also Ohm's law, must, on the principles of the conservation of energy, also explain the induction of currents.

The magnetic rotation of the plane of polarisation of light does not depend on the structure of the ether, or on the magnetic field itself, but is a result of the atomic configuration of the matter in the field modified by the magnetism. It is generally recognised as caused by something in the field rotating round the direction of the magnetic lines of force. Now the vortex atom, as usually pictured, is incapable of exhibiting this property. It is, however, an interesting fact, and one which I hope to demonstrate to this Section during the meeting, that a vortex ring can have two simultaneous and independent cyclic motions—one the ordinary one, and another which is capable of producing just the action on light which shows itself as a rotation of the plane of polarisation. The motion is rather a complicated one to describe without a diagram, but an idea of its nature may be obtained by considering the case of a straight cylindrical vortex. The ordinary straight vortex consists, as every one knows, of a cylinder of fluid revolving like a solid, and surrounded by a fluid in irrotational motion. In the core the velocity increases from zero at the axis to a maximum at its surface. Thence it continuously decreases in the outer fluid as the distance increases. Everywhere the motion is in a plane perpendicular to the axis. Let us now consider a quite different kind of vortical motion. Suppose the fluid is flowing along the core like a viscous fluid through a pipe: the velocity is zero at the surface and a maximum at the axis. Everywhere it is parallel to the axis, the vortex lines are circles in planes perpendicular to the axis, and concentric with it. Since the velocity at the surface of the core is zero, the surrounding fluid is also at rest. Now superpose this motion on the previous one, and it will be found to be steady. If a short length of this vortex be supposed cut off, bent into the shape of a circle and the ends joined, we shall have very a rough idea of the compound vortex ring of which I speak. I say a very rough idea, because the actual state of motion in a ring vortex or a Hill's vortex is not quite so simple as the analogy might lead one to think.

Now a compound vortex atom of this kind is just what we want to produce rotation of the plane of polarisation of light. The light passing through such a vortex has the direction of vibration twisted in the wave front. In ordinary matter no such rotation is produced, because the various atoms are indifferently directed, and they neutralise each other's effects. Let, however, a magnetic field be produced, and they will range themselves so that, on the average, the primary[1] circulations through the apertures will point in the direction of the field. Consequently the average direction of the secondary spin will be in planes perpendicular to it, and will rotate the plane of polarisation of any light whose wave front passes them. The rotation is produced only in the light which is transmitted *through* the vortex. The rotation, therefore, is a resultant effect. In fact it is clear that in the case of refraction the optical media belong to the type in which every particle transmits the light, and not to the type in which refraction is produced by opaque bodies embedded in the ether. The atoms are only opaque if they contain vacuous cores. The question of the grip of the particles on the ether does not enter, but difference of quality—showing itself in refraction and dispersion—is due to difference in average rotational quasi-elasticity produced by the atomic circulations, and possibly absorption is due to precessional and nutational motion set up by the secondary spins. These, however, are perhaps rather vague speculations.

Instead of attempting to invent ethers, to deduce their properties from their specifications, and then seeing whether they fit in with experience, we may begin half-way. We may assume different forms for the function giving the energy of the medium when disturbed, apply general dynamical methods, and distinguish between those which are capable of explaining the phenomena we are investigating and those which are not. Invention is then called upon to devise a medium for which the desired energy-function is appropriate. This was the method applied by MacCullagh to the luminiferous ether. He obtained an algebraical form of the energy function which completely satisfied the conditions for a luminiferous ether; its essential property being that the energy depended only on the rotational displacements of its small parts. He was unable, however, to picture a stable material medium which would possess this property. We recognise now that such a medium is possible if the rotational rigidity is produced by intrinsic motions in the small parts of the medium of a gyrostatic nature. In a most masterly manner Larmor ("A Dynamical Theory of the Electric and Luminiferous Medium," *Phil. Trans.*, 1894) has recently investigated by general dynamical methods the possibility of explaining electric and magnetic phenomena by means of the same energy function. Electric lines of force are rotational filaments in the ether,[1] similar in fact to those I suggested at Bath, while a magnetic field consists of a flow of the ether. The same difficulty in accounting for electro-dynamic induction arises, but the general form of the equations for the electrodynamic and magnetic fields are the same as those generally received.

Towards the end of this paper he is led to postulate a theory of electrons whose convection through the ether constitutes an electric current. Two rotating round each other are supposed to produce the same effect as a vortex ring. The mass of ordinary matter is attributed to the electric inertia of these electrons. The electron itself is a centre or nucleus of rotational strain. If I express a doubt as to the possibility of the existence of these nuclei as specified, I do so with great diffidence.[2] Whether they can or cannot exist, however, the general results of the investigation are not affected.

Since this paper was published Larmor has read a second one on the same subject before the Royal Society, developing further his theory of the electron. The publication of this will be awaited with interest. It is impossible in an address such as this to go *seriatim* into the numerous points which he takes up and illuminates, because the mathematical treatment of the general question does not lend itself easily to oral exposition even to an audience composed of professed mathematicians. There is no doubt but that this paper has put the theory of a rotationally elastic ether—and with it that of a fluid vortex ether—on a sounder basis, and will lead to its discussion and elucidation by a wider circle of investigators.

One further class of physical phenomena yet remains, viz. those of gravitation. The ether must be capable of transmitting gravitational forces as well as electric and optical effects. Does the rotational ether give any promise of doing this? No satisfactory explanation of gravitation on any theory has yet been offered. Perhaps the least unsatisfactory is that depending on the vortex atom theory of matter ("On the Problem of Two Pulsating Spheres in a Fluid," *Proc. Camb. Phil. Soc.*, iii. p. 283), which attributes it to pulsations of hollow vortex atoms. But this necessitates that they should all pulsate with the same period and in the same phase. It is very difficult to conceive how this can happen, unless, as Larmor suggests, all matter is built

[1] "Primary" refers to the motion as usually understood; "secondary" to the superposed motion described above.

[1] The necessity that the filaments shall be in pairs does not seem to be recognised. This is, however, essential. Moreover, if the complementary terminations of the filaments between (say) a plate condenser be placed elsewhere than in the same region, the filaments between the plates must rotate as a whole; that is, an electric field would always be combined with a magnetic one.

[2] It would appear that the same results would flow if two particles oppositely electrified, *i.e.* joined by two complementary filaments, as already described, were to rotate round each other.

up of constant elements like his electrons, whose periods are necessarily all alike. It is possible that the vortex cell theory of the ether, of which I have already spoken, may suffice to explain gravitation also. The cells, besides their rotational rigidity, have, in addition, as we saw, a peculiar elasticity of form. To get an idea of how this theory may account for weight, let us suppose the simplest case where all the cells are exactly alike, and the medium is in equilibrium. Now suppose one of the cells begins to grow. It forces the medium away on all sides; the cells will be distorted in some definite way, and a strain set up. Further, this strain will be transmitted from the centre, so that the total amount across any concentric sphere will be the same. Stresses will therefore be set up in the whole medium. If a second cell begins to grow at another place it will produce also a state of strain, the total strain depending on the presence of both. The stresses called into play in the medium will produce a stress between the bodies, but it is questionable whether it would be inversely as the square of the distance. Whether it would be an attraction or repulsion can only be determined by mathematical investigation. The problem is quite determinate, though probably a very difficult one, and would be of mathematical interest quite apart from its physical importance. Since apparently the phenomena of gravitation have no direct interaction with those of light and electricity, whilst the mind rejects the possibility of two different media occupying the same space, we seem driven to look for it in an independent structure of the same medium. Such a structure is already to our hands, with its effects waiting to be determined. It may well be that it may prove to be the cause we are seeking.

The rapid survey I have attempted to make is no doubt a medley of suppositions and inferences combined with some sound deductions. This is the necessary consequence of a prospecting survey in a region whose surface has been merely scratched by pioneers. My object has been to show that this theory of an ether, based on a primitive perfect fluid, is one which shows very promising signs of being able to explain the various physical phenomena of our material universe. Probably, nay certainly, the explanations suggested are not all the true ones. Some will have to be given up, others modified with further knowledge. We cannot proceed to particularise in our secondary hypotheses until we know more about the properties of such media as we have been considering. Every special problem solved in vortex motion puts us in a position to form clearer ideas of what can and what cannot happen. The whole question of vortex aggregates and their interactions is practically untouched, and a rich field is open for mathematical investigation in this portion only of the subject. In all cases, whether a fluid ether is an actual fact or not, the results obtained will be of special interest as types of fluid motion. It is at present a subject in which the mathematicians must lead the attack. I shall have attained my object in choosing this subject for my address, if by it I can induce some of our younger mathematicians to take it up and work out its details.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. RAPHAEL MELDOLA, F.R.S., F.I.C., FOR. SEC. C.S., PRESIDENT OF THE SECTION.

The State of Chemical Science in 1851.

In order to estimate the progress of chemical science since the year 1851, when the British Association last met in this town, it will be of interest for us to endeavour to place ourselves in the position of those who took part in the proceedings of Section B on that occasion. Perhaps the best way of performing this retrograde feat will be to confront the fundamental doctrines of modern chemistry with the state of chemical theory at that period, because at any point in the history of a science the theoretical conceptions in vogue—whether these conceptions have survived to the present time or not—may be taken as the abstract summation of the facts, *i.e.* of the real and tangible knowledge existing at the period chosen as the standard of reference.

Without going too far back in time I may remind you that in 1811 the atomic theory of the chemists was grafted on to the kindred science of physics through the enunciation of the law associated with the name of Avogadro di Quaregna. The rationalising of this law had been accomplished in 1845, but the kinetic theory of gases, which had been foreshadowed by D. Bernoulli in 1738, and in later times by Herapath, Joule, and Krönig, lay buried in the archives of the Royal Society until recently unearthed by Lord Rayleigh and given to the world in 1892 under the authorship of Waterston, the legitimate discoverer. The later developments of this theory did not take place till after the last Ipswich meeting, viz. in 1857-62, by Clausius, and by Clerk Maxwell in 1860-67. Thus the kinetic theory of gases of the physicists had not in 1851 acquired the full significance for chemists which it now possesses: the hypothesis of Avogadro was available, analogous conceptions had been advanced by Davy in 1812, and by Ampere in 1814; but no substantial chemical reasons for its adoption were adduced until the year 1846, when Laurent published his work on the law of even numbers of atoms and the nature of the elements in the free state (*Ann. Chim. Phys.* [3], 18, 266).

The so-called "New Chemistry" with which students of the present time are familiar was, in fact, being evolved about the period when the British Association last assembled at Ipswich; but it was not till some years later, and then chiefly through the writings of Laurent and Gerhardt, that the modern views became accepted. It is of interest to note in passing that the nomenclature of organic compounds formed the subject of a report by Dr. Daubeny at that meeting in which he says:—"It has struck me as a matter of surprise that none of the British treatises on chemistry with which I am acquainted should contain any rules to guide us, either in affixing names to substances newly discovered or in divining the nature and relations of bodies from the appellations attached to them. Nor do I find this deficiency supplied in a manner which to me appears satisfactory when I turn to the writings of continental chemists." In a subsequent portion of the report Dr. Daubeny adds:—"No name ought, for the sake of convenience, to exceed in length six or seven syllables." I am afraid the requirements of modern organic chemistry have not enabled us to comply with this condition.

Among other physical discoveries which have exerted an important influence on chemical theory the law of Dulong and Petit, indicating the relationship between specific heat and atomic weight, had been announced in 1819, had been subsequently extended to compounds by Neumann, and still later had been placed upon a sure basis by the classical researches of Regnault in 1839. But here, again, it was not till after 1851 that Cannizzaro (1858) gave this law the importance which it now possesses in connection with the determination of atomic weights. Thermo-chemistry as a distinct branch of our science may also be considered to have arisen since 1851, although the foundations were laid before this period by the work of Favre and Silbermann, Andrews, Graham, and especially Hess, whose important generalisation was announced in 1840, and whose claim to just recognition in the history of physical chemistry has been ably advocated in recent times by Ostwald. But the elaboration of thermo-chemical facts and views in the light of the dynamical theory of heat was first commenced in 1853 by Julius Thomsen, and has since been carried on concurrently with the work of Berthelot in the same field which the latter investigator entered in 1865. Electro-chemistry in 1851 was in an equally rudimentary condition Davy had published his electro-chemical theory in 1807, and in 1812 Berzelius had put forward those views on electric affinity which became the basis of his dualistic system of formulation. In 1833 Faraday announced his famous law of electro-chemical equivalence, which gave a fatal blow to the conception of Berzelius, and which later (1839-40) was made use of by Daniell in order to show the untenability of the dualistic system. By 1851 the views of Berzelius had been abandoned, and, so far as chemical theory is concerned, the whole subject may be considered to have been in abeyance at that time. It is of interest to note, however, that in that year Williamson advanced on quite distinct grounds his now well-known theory of atomic interchange between molecules, which theory in a more extended form was developed independently from the physical side and applied to electrolytes by Clausius in 1857 The modern theory of electrolysis associated with the names of Arrhenius, van 't Hoff, and Ostwald is of comparatively recent growth. It appears that Hittorf in 1878 was the first to point out the relationship between electrolytic conductivity and chemical activity, this same author as far back as 1856 having combated the prevailing view that the electric current during electrolysis does the work of overcoming the affinities of the ions. Arrhenius formulated his theory of electrolytic dissociation in

1887, Planck having almost simultaneously arrived at similar views on other grounds.

Closely connected with electrolysis is the question of the constitution of solutions, and here again a convergence of work from several distinct fields has led to the creation of a new branch of physical chemistry which may be considered a modern growth. The relationship between the strength of a solution and its freezing point had been discovered by Blagden towards the end of the last century, but in 1851 chemists had no notion that this observation would have any influence on the future development of their science. Another decade elapsed before the law was rediscovered by Rüdorff (1861), and ten years later was further elaborated by de Coppet. Raoult published his first work on the freezing point of solutions in 1882, and two years later the relationship between osmotic pressure and the lowering of freezing point was established by H. de Vries, who first approached the subject as a physiologist, through observations on the cell contents of living plants. As the work done in connection with osmotic pressure has had such an important influence on the "dissociation" theory of solutions, it will be of interest to note that at the last Ipswich meeting Thomas Graham made a communication on liquid diffusion, in which he "gave a view of some of the unpublished results, to ascertain whether solutions of saline bodies had a power of diffusion among liquids, especially water." In 1877 Pfeffer, who, like de Vries, entered the field from the botanical-physiological side, succeeded in effecting the measurement of osmotic pressure. Ten years later van 't Hoff formulated the modern dissociation theory of solution by applying to dissolved substances the laws of Boyle, Gay-Lussac, and Avogadro, the law of osmotic pressure, and Raoult's law connecting the depression of freezing point with molecular weight, thus laying the foundation of a doctrine which, whether destined to survive in its present form or not, has certainly exerted a great influence on contemporary chemical thought.

Consider, further, the state of knowledge in 1851 concerning such leading principles as dissociation or thermolysis, mass action, and chemical equilibrium. Abnormal vapour densities had been observed by Avogadro in 1811, and by Ampère in 1814. Grove had dissociated water vapour by heat in 1847, but the first great advance was made ten years later by Sainte-Claire Deville, from whose work has emanated our existing knowledge of this subject. I may add that the application of this principle to explain the cases of abnormal vapour density was made in 1858 by Kopp, Kekulé, and Cannizzaro almost simultaneously; but, strangely enough, this explanation was not accepted by Deville himself. The subsequent stages are subjects of modern history. The current views on mass action were foreshadowed, as is well known, by Berthollet in his "Statique Chimique," published in 1803, but no great advance had been made when the British Association last met here. The subject first began to assume a quantitative aspect through the researches of Bunsen and Debus in 1853, and was much advanced by Gladstone in 1865 and by Harcourt and Esson a year later. Guldberg and Waage published their classical work on this subject in 1867.

Equally striking will appear the advances made since 1851 if we consider that the whole subject of spectrum analysis, which brings our science into relationship with astronomy, has been called into existence since that date. The celebrated work of Bunsen and Kirchhoff was not published till 1859. Neither can I refrain from reminding you that the coal-tar colour industry, with which I have been to a small extent connected, was started into activity by Perkin's discovery of mauve in 1856; the reaction of this industry on the development of organic chemistry is now too well known to require further mention. In that great domain also which brings chemistry into relationship with biology the progress has been so great that it is not going beyond the limits of accuracy to state that a new science has been created. Pasteur began his studies on fermentation in 1857, and out of that work has arisen the science of bacteriology, with its multifarious and far-reaching consequences. As this chapter of chemical history forms the subject of one of the evening discourses at the present meeting, it is unnecessary to dwell further upon it now. One other generalisation may be chronicled among the great developments achieved since 1851. I refer to the periodic law connecting the atomic weights of the chemical elements with their physical and chemical properties. Attempts to establish numerical relationships in the case of isolated groups of elements had been made by Döbereiner in 1817, by Gmelin in 1826, and again by Döbereiner in 1829. The triad system of grouping was further developed by Dumas in 1851. I am informed by Dr. Gladstone that at the last Ipswich meeting Dumas' speculations in this direction excited much interest. All the later steps of importance have, however, been made since that time, viz. by de Chancourtois in 1862, the "law of octaves" by Newlands in 1864, the periodic law by Mendeléeff, and almost contemporaneously by Lothar Meyer in 1869.

I have been tempted into giving this necessarily fragmentary and possibly tedious historical sketch because it is approaching half a century since the British Association visited this town, and the opportunity seemed favourable for going through that process which in commercial affairs is called "taking stock." The result speaks for itself. Our students of the present time who are nourished intellectually by these doctrines should be made to realise how rapid has been their development. The pioneers of our science, on whose shoulders we stand—and many of whom are happily still among us—will derive satisfaction from the retrospect, and will admit that their labours have borne goodly fruit. It is not, however, simply for the purpose of recording this enormous progress that I have ventured to assume the office of stock-taker. The year 1851 may be regarded as occurring towards the close of one epoch and the dawn of a new era in chemical history. Consider broadly the state of organic chemistry at that time. There is no occasion for going into detail, even if time admitted, because our literature has recently been enriched by the concise and excellent historical works of Schorlemmer and of Ernst von Meyer. It will suffice to mention that the work and writings of Liebig, Berzelius, Wöhler, Dumas, Gay-Lussac, Bunsen, and others had given us the leading ideas of isomerism, substitution, compound radicles, and types. Wurtz and Hofmann had just discovered the organic ammonias; Williamson that same year made known his celebrated work on the ethers; and Gerhardt discovered the acid anhydrides a year later. The newer theory of type was undergoing development by Gerhardt and his followers; the mature results were published in the fourth volume of the "Traité de Chimie" in 1856. In this country the theory was much advanced by the writings of Odling and Williamson.

SUBSEQUENT DEVELOPMENT OF CHEMISTRY ALONG TWO LINES.

The new era which was dawning upon us in 1851 was that of structural or constitutional chemistry, based on the doctrine of the valency of the atoms. It is well known that this conception was broached by Frankland in 1852, as the result of his investigations on the organo-metallic compounds. But it was not till 1858 that Kekulé, who had previously done much to develop the theory of types, and Couper, almost simultaneously, recognised the quadrivalent character of carbon. To attempt to give anything approaching an adequate notion of the subsequent influence of this idea on the progress of organic chemistry would be tantamount to reviewing the present condition of that subject. I imagine that no conception more prolific of results has ever been introduced into any department of science. If we glance back along the stream it will be seen that shortly after the last meeting here the course of discovery began to concentrate itself into two channels. In one we now find the results of the confluent labours of those who have regarded our science from its physical side. In the other channel is flowing the tide of discovery arising from the valency doctrine and its extension to the structure of chemical molecules. The two channels are at present fairly parallel and not far apart; an occasional explorer endeavours now and again to make a cross-cut so as to put the streams into communication. The currents in both are running very rapidly, and the worker who has embarked on one or the other finds himself hurried along at such a pace that there is hardly breathing time to step ashore and see what his neighbours are doing. It speaks well for the fertility of the conception of valency that the current in this channel is flowing with unabated vigour, although its catchment area—to pursue the metaphor—is by no means so extensive as that of the neighbouring stream.

The modern tendency to specialisation, which is a necessity arising from the large number of workers and the rapid multiplication of results, is apparently in the two directions indicated. We have one class of workers dealing with the physics of matter in relation to general chemical properties, and another class of investigators concerning themselves with the special properties of individual compounds and classes of compounds—with atomic idiosyncrasies. The workers of one class are differentiating while their colleagues are integrating. It would be nothing less than unscientific to institute a comparison between the relative

merits of the two methods; both are necessary for the development of our science. All methods of attacking the unknown are equally welcomed. In some cases physical methods are available, in other cases purely chemical methods have alone been found of use. There is no antagonism, but co-operation. If the results of the two methods are sometimes at variance it is simply because we have not known how to interpret them. The physical chemist has adopted the results of the application of chemical methods of determining "constitution," and is endeavouring to furnish us with new weapons for attacking this same problem. The chemist who is seeking to unravel the architecture of molecules is dependent at the outset upon physical methods of determining the relative weights of his molecules. The worker who is bringing about new atomic groupings is furnishing material for the further development of generalisations from which new methods applicable to the problem of chemical structure may again be evolved. The physical chemist sometimes from the broadness of his view is apt to overlook or to minimise the importance of chemical individuality. On the other hand the chemist who is studying the numberless potentialities of combination resident in the atoms, and who has grasped to the full extent their marvellous individualities, is equally liable to forget that there are connecting relationships as well as specific differences in the properties of elements and compounds. These are but the mental traits—the unconscious bias engendered by the necessary specialisation of work to which I have referred, and which is observable in every department of scientific labour.

THE PRESENT STATE OF STRUCTURAL CHEMISTRY.

The success attending the application of the doctrine of valency to the compounds of carbon has helped its extension to all compounds formed by other elements, and the student of the present day is taught to use structural formulæ as the A B C of his science. It is, I think, generally recognised among chemists that this doctrine in its present state is empirical, but it does not appear to me that this point is sufficiently insisted upon in chemical teaching. I do not mean to assert that for the last thirty years chemists have been pursuing a phantom; neither do I think that we should be justified in applying to this doctrine the words applied to its forerunner, the "types" of Gerhardt, by Lothar Meyer, who says that these "have rendered great service in the development of the science, but they can only be regarded as a part of the scaffolding which was removed when the erection of the system of organic chemistry had made sufficient progress to be able to dispense with it" ("Modern Theories of Chemistry," p. 194.) It appears to me, on the contrary, that there is a physical reality underlying the conception of valency, if for no other reason because of the conformability of this property of the atoms to the periodic law. But the doctrine as it stands is empirical in so far that it is only representative and not explanatory. Frankland and Kekulé have given us a great truth, but its very success is now making it more and more obvious that it is a truth which is pressing for further development from the physical side. If we are asked why CO exists, and why CH_2 and CCl_2 do not, together with innumerable similar questions which the inquisitive mind will raise, we get no light from this doctrine. If any over-sanguine disciple goes so far as to assert that all the possible compounds of the elements indicated by their valency are capable of existence, and will sooner or later be prepared, he will, I imagine, find himself rapidly travelling away from the region of fact.

There is something to be reckoned with besides valency. The one great desideratum of modern chemistry is unquestionably a physical or mechanical interpretation of the combining capacities of the atoms. Attempts at the construction of such theories have been made, and thus far only in a tentative way, and these views cannot be said to have yet come within the domain of practical chemical politics. I have in mind, among other suggestions, the dynamical theory of van 't Hoff published in 1881 ("Ansichten über die organische Chemie"), the theory of electric charges on the atoms broached by Johnstone Stoney in 1874, and so ably advocated by the late Prof. v. Helmholtz in his Faraday lecture in 1881, and the electric polar theory of Victor Meyer and Riecke, published in 1888 ("Einige Bemerkungen über den Kohlenstoffatom und die Valenz," *Ber.*, 21, pp. 946, 1620).

Pending the rationalisation of the doctrine of valency its promulgation must continue in its present form. Its services in the construction of rational formulæ, especially within the limits of isomerism, have been incalculable. It is the ladder by which we have climbed to the present brilliant achievements in chemical synthesis, and we are not in a position to perform the ungracious task of kicking it away. In recalling attention to its weaknesses I am only putting myself in the position of the physician who diagnoses his patient's case with the ulterior object of getting him strengthened. There can be no doubt that renewed vitality has been given to the doctrine by the conceptions of tautomerism and desmotropy, formulated by Conrad Laar in 1885, and by Paul Jacobson in 1887. The importance of these ideas is becoming more evident with the advancement of chemical discovery. Any attempt to break down the rigidly statical conception of our structural formulæ appears to me to be a step in the right direction. Then, again, I will remind you of the prolific development of the doctrine in the hands of Le Bel and van 't Hoff by the introduction of the stereochemical hypothesis in 1874—unquestionably the greatest advance in structural chemistry since the recognition of the quadrivalent character of the carbon atom. If evidence be required that there is a physical reality underlying the conception of valency, we need only point to the close accordance of this notion of the asymmetric carbon atom with the facts of so-called "physical isomerism" and the splendid results that have followed from its introduction into our science, especially in the field of carbohydrates through the investigations of Emil Fischer and his pupils. In other directions the stereochemical hypothesis has proved to be a most suggestive guide. It was applied by Prof. v. Baeyer in 1885 (*Ber.*, 18, 2277) to explain the conditions of stability or instability of certain atomic groupings, such as the explosiveness of polyacetylene compounds and the stability of penta- and hexa-cyclic systems. Again, in 1888 this eminent chemist showed its fertility in a series of brilliant researches upon benzene derivatives (*Ann.*, 137, 158, and subsequent papers). Nor can I omit to mention the great impetus given in this field by the classical work of Wislicenus, who in 1887 applied the hypothesis to unsaturated compounds and to cyclic systems with remarkable success ("Ueber die räumliche Anordnung der Atome in organischen Molekulen," &c.). Quite recently Victor Meyer and J. Sudborough have shown that the ability of certain derivatives of benzoic and naphthoic acids to form ethers is governed by stereochemical considerations (*Ber.*, 27, 510, 1580, 3146, and 28, 182, 1254). But I must avoid the temptation to enlarge upon this theme because the whole subject has been recently brought together by C. A. Bischoff in his "Handbuch der Stereochemie" (Frankfurt, 1893–94), a work to which all who are interested in the subject will naturally turn for reference.

While the present advanced state of structural chemistry may thus be looked upon as the outcome of the conceptions of Frankland and Kekulé, it may be well to bear in mind that the idea of structure is not *necessarily* bound up with the hypothesis of valency in its present form. Indeed, some advance had been made in representing "constitution," especially by Kolbe, before the formal introduction of this hypothesis. The two ideas have grown up together, but the experimental evidence that in any molecule the atoms are grouped together in a particular way is really independent of any theory of valency. It is only after this evidence has been acquired, either by analysis or synthesis, that we proceed to apply the hypothesis in building up the structural formula. It is of course legitimate to assume the truth of the hypothesis, and to endeavour by its use to convert an empirical into a rational formula: but this method generally gives us a choice of formulæ from which the true one can only be selected by further experimental investigation. Even within the narrower limits of isomerism it is by no means certain that all the modifications of a compound indicated by hypothesis are actually capable of existence. There is, for example, evidence that some of the "position isomerides" among the derivatives of mono- and poly-cyclic compounds are too unstable to exist; a fact which in itself is sufficient to indicate the necessity for a revision and extension of our notions of valency. Thus, by way of illustration, there is nothing in the hypothesis to indicate why orthoquinones of the benzene series should not be capable of existence; yet it is a fact that in spite of all efforts such compounds have never been obtained. The conditions essential for the existence of these compounds appear to be that the hydrogen of the benzene ring should be replaced by acid substituents such as oxygen, hydroxyl, chlorine, or bromine. Under these circumstances, as Zincke has shown (*Ber.*, 20, 1776), tetrachlor and tetrabrom-orthobenzoquinone are stable compounds. So also the interesting researches of Nietzki have proved that in such a compound as rhodizonic acid (*Ibid.*, 19, 308, and 23, 3136) ortho-

quinone oxygen atoms are present. But there is nothing in the doctrine of valency which leads us to suspect that these orthoquinone derivatives can exist while their parent compound resists all attempts at isolation. I am aware that it is dangerous to argue from negative evidence, and it would be rash to assert that these orthoquinones will never be obtained. But even in the present state of knowledge it may be distinctly affirmed that the methods which readily furnish an orthoquinone of naphthalene completely fail in the case of benzene, and it is just on such points as this that the inadequacy of the hypothesis becomes apparent. In other words, the doctrine fails in the fundamental requirement of a scientific theory; in its present form it gives us no power of prevision: it hints at possibilities of atomic groupings, but it does not tell us *à priori* which of these groupings are likely to be stable and which unstable. I am not without hope that the next great advance in the required direction may yet come from the stereochemical extension of the hypothesis, although the attempts which have hitherto been made to supply its deficiencies cannot but be regarded as more or less tentative.

THE NEW THEORY OF ABSTRACT TYPES.

I will venture, in the next place, to direct attention to a modern development of structural chemistry which will help to illustrate still further some of the points raised. For many years we have been in the habit of abstracting from our structural formulæ certain ideal complexes of atoms which we consider to represent the nucleus or type from which the compound of known constitution is derived. In other words, the hypothesis of valency which was developed originally from Gerhardt's types is now leading us back to another theory of types based upon a more intimate knowledge of atomic grouping within the molecule. In some cases these types have been shown to be capable of existence: in others they are still ideal. Used in this way the doctrine of valency is most suggestive, but at the same time its lack of prevision is constantly forcing itself upon the attention of chemical investigators. The parent compound has sometimes been known before its derivatives, as in the case of ammonia, which was known long before the organic amines and amides. In other instances the derivatives were obtained before the type was isolated, as in the case of the hydrazines, which were characterised by Emil Fischer in 1875, and the hydrazo-compounds, which have been known since 1863, while hydrazine itself was first obtained by Curtius in 1887. Phenylazimide was discovered by Griess in 1864, and many representatives of this group have been since prepared; but the parent compound, hydrazoic acid, was only isolated by Curtius in 1890. Derivatives of triazole and tetrazole were obtained by Bladin in 1885; the types were isolated by this chemist and by Andreocci in 1892. Pyrazole derivatives were prepared by Knorr in 1883; pyrazole itself was not isolated till 1889, by Buchner. Alkyl nitramides were discovered by Franchimont and Klobbie many years before the typical compound, nitramide, $NO_2.NH_2$, which was isolated last year by Thiele and Lachman (*Ber.*, 27, 1909). Examples might be multiplied to a formidable extent, but enough have been given to illustrate the principle of the erection of types, which were at first imaginary, but which have since become real. The utility of the hypothesis is undeniable in these cases, and we are justified in pushing it to its extreme limits. But no chemist, even if endowed with prophetic instinct, could have certainly foretold six years ago that the type of Griess' "triazobenzene" would be capable of free existence, and still less that when obtained it would prove to be a strong acid. The fact, established by Curtius, that the group $\begin{matrix} N \\ N \end{matrix}\!\!>\!N\text{-}$ functions in chemical molecules like the atom of chlorine is certainly among the most striking of recent discoveries. Only last year the list of nitrogen compounds was enriched by the addition of $CO(N_3)_2$, the nitrogen analogue of phosgene (Curtius, *Ber.*, 27, 2684).

These illustrations, drawn from the compounds of nitrogen, will serve to bring out the wonderful development which our knowledge of the chemistry of this element has undergone within the last few years. I might be tempted here into a digression on the general bearing of the very striking fact that an element comparatively inert in the free state should be so remarkably active in combination, but I must keep to the main topic, as by means of these compounds it is possible to illustrate still further both the strength and the weakness of our modern conceptions of chemical structure. Consider some of the undiscovered compounds which are foreshadowed by the process of ideal abstraction of types. The azoxy-compounds contain the complex $-N-N-$ with O bonded to both N (i.e. $-N-N-$ over $\diagdown O \diagup$) or $-N=N-$ with $\ddot{}\ O$. The types would be $HN-NH$ over $\diagdown O \diagup$ or $HN=NH$ with $\ddot{}\ O$. The first of these formulæ represents the unknown dihydro-nitrous oxide. The azo-compounds are derivatives of the hypothetical diimide $HN:NH$. An attempt to prepare this compound from azodicarbonic acid (Thiele, *Ann.*, 271, 130) resulted in the formation of hydrazine. The diethyl-derivative may have been obtained by Harries (*Ber.*, 27, 2276), but this is doubtful. It is at present inexplicable why compounds in which the group $\cdot N:N\cdot$ is in combination with aromatic radicles should be so remarkably stable, while the parent compound appears to be incapable of existence. The addition of two atoms of hydrogen converts this type again into a stable compound. There is nothing in the structural formulæ to indicate these facts. The amidines are stable compounds, and the so-called "anhydro-bases," or imidazoles, are remarkably stable; the parent compound $HC\begin{smallmatrix} \diagup NH \\ \diagdown NH_2 \end{smallmatrix}$, has not been obtained, while its amido-derivative, $H_2N.C\begin{smallmatrix} \diagup\!\!\diagup NH \\ \diagdown NH_2 \end{smallmatrix}$, is the well-known substance guanidine. The isodiazo-compounds recently discovered by Schraube and Schmidt and by Bamberger (*Ibid.*, 27, 514, 679, &c.) are possibly derivatives of the hypothetical substance $O:N.NH_2$, which might be named nitrosamide. Why this compound should not exist as well as nitramide is another question raised by the principle of abstract types. The carbizines were formerly regarded as derivatives of the compounds $CO\begin{smallmatrix} \diagup NH \\ \cdot \\ \diagdown NH \end{smallmatrix}$ and $CS\begin{smallmatrix} \diagup NH \\ \cdot \\ NH_2 \end{smallmatrix}$ (Fischer, *Ann.*, 212, 326; Freund and Goldsmith, *Ber.*, 21, 2456). Although this structure has now been disproved the possible existence of the types has been suggested. Carbizine and thiocarbizine differ from urea and thiocarbamide only by two atoms of hydrogen. These types have not been isolated: if they are incapable of existence the current views of molecular structure give no suggestion of a reason. The diazoamides are derivatives of the hypothetical $H_2N.NH.NH_2$ or $HN:N.NH_2$, compounds which Curtius speaks of as the propane and propylene of the nitrogen series. The latter complex was at one time thought to exist in diazohippuramide (*Ber.*, 24, 3342. This has since been shown to be hippurazide, *i.e.* a derivative of N_3H, *Ber.*, 27, 779), and a biacidyl derivative of the former type has also been obtained (*Ibid.*, 3344). Both these types await isolation if they are capable of existence. I may add that several attempts to convert diazoamides into dihydro-derivatives by mild alkaline reduction have led me to doubt whether this nitrogen chain can exist in combination with hydrocarbon radicles. The bisdiazoamides of H. v. Pechmann and Frobenius (*Ber.*, 27, 898) are derivatives of the 5-atom chain $H_2N.NH.NH.NH.NH_2$ or $HN:N.NH.N:NH$, a type which hardly seems likely to be of sufficient stability to exist. The tetrazones of Emil Fischer have for their type the 4-atom chain $H_2N.N:N.NH_2$ or $H_2N.NH.NH.NH_2$, of which the free existence is equally problematical, although a derivative containing the chain $-N:N.NH.NH-$ has been obtained by Curtius (*Ibid.*, 26, 1263). Hydrazoic acid may be regarded as a derivative of triimide, $HN\begin{smallmatrix} \diagup NH \\ \diagdown NH \end{smallmatrix}$, but this type appears to be also incapable of isolation (Curtius, *Ber.*, 26, 407). The hydrazidines or formazyls of Pinner (*Ber.*, 17, 182) and of H. v. Pechmann (*Ibid.*, 25, 3175), have for their parent compound the hypothetical substance $H_2N.N:CH.N:NH$. In 1888 Limpricht described certain azo-compounds (*Ibid.*, 21, 3422) which, if possessing the structure assigned by that author, must be regarded as derivatives of diamidotetrimide:

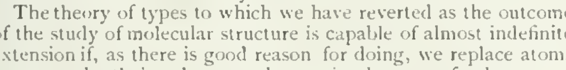
$$\begin{matrix} HN-NH \\ | \qquad | \\ HN-NH \end{matrix} \qquad\qquad \begin{matrix} H_2N.N-N \\ | \qquad | \\ H_2N.N-N \end{matrix}$$

Both these types are at present imaginary; whether it is possible for cyclic nitrogen systems to exist we have no means of knowing—all that can be said is that they have never yet been obtained. It is possible, as I pointed out in 1890 at the Leeds meeting of

the British Association, that mixed diazoamides may be derivatives of such a 4-atom ring.

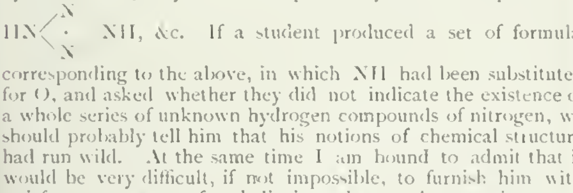
Any chemist who has followed the later developments of the chemistry of nitrogen could supply numerous other instances of undiscovered types. A chapter on the unknown compounds of this element would furnish quite an exciting addition to many of those books which are turned out at the present time in such profusion to meet the requirements of this or that examining body. I have selected my examples from these compounds simply because I can claim some of them as personal acquaintances. It would be easy to make use of carbon compounds for the same purpose, but it is unnecessary to multiply details. It has frequently happened in the history of science that a well-considered statement of the shortcomings of a theory has led to its much-desired extension. This is my hope in venturing to point out one of the chief deficiencies in the structural chemistry of the present time. I am afraid that I have handled the case badly, but I am bound to confess that I am influenced by the same feelings as those which prevent us from judging an old and well-tried friend too severely.

The theory of types to which we have reverted as the outcome of the study of molecular structure is capable of almost indefinite extension if, as there is good reason for doing, we replace atoms or groups by their valency analogues in the way of other atoms or groups of atoms. The facts that in cyclic systems N can replace CH (benzene and pyridine), that O, S, and NH are analogues in furfurane, thiophene, and pyrrole, are among the most familiar examples. The remarkable iodo- and iodoso-compounds recently discovered by Victor Meyer and his colleagues are the first known instances in which the trivalent atom of iodine has been shown to be the valency analogue of nitrogen in organic combination. Pushing this principle to the extreme we get further suggestions for new groupings, but, as before, no certainty of prevision. Thus, if nitrogen formed the oxide N_2O_2 the series might be written:



Of course these formulæ are more or less conjectural, being based on valency only. But since nitrous oxide is the analogue of hydrazoic acid, they hint at the possibility of such compounds as

 &c. If a student produced a set of formulæ corresponding to the above, in which NH had been substituted for O, and asked whether they did not indicate the existence of a whole series of unknown hydrogen compounds of nitrogen, we should probably tell him that his notions of chemical structure had run wild. At the same time I am bound to admit that it would be very difficult, if not impossible, to furnish him with satisfactory reasons for believing that such groupings are improbable. Compare again the series:



The first is urea; the second, third, fourth, fifth (methylene diamine), and sixth are unknown; the seventh is the remarkably interesting diazomethane discovered last year by H. v. Pechmann (*Ber.*, 27, 1888). The last compound, dinitromethane, is known in the form of its salts, but appears to be incapable of existence in the free state. There is nothing expressed or implied in the existing theory of chemical structure to explain why dinitromethane is unstable while trinitromethane is stable, and mono- and tetranitromethane so stable as to admit of being distilled without decomposition. Chemists will form their own views as to the possibility or impossibility of such a series as this being completed. Whether there would be a concordance of opinion I will not venture to say; but any chemist who expressed either belief or disbelief with regard to any special member would, I imagine, have great difficulty in giving a scientific reason for the faith which is in him. At the most, he would have only the very unsafe guide of analogy to fall back upon. Perhaps by the time the British Association holds its next meeting at Ipswich it will have become possible to prove that one particular configuration of certain atoms is possible and another configuration impossible. Then will have been achieved that great advance for which we are waiting the reunion of the two streams into which our science began to diverge shortly after the last Ipswich meeting.

The present position of structural chemistry may be summed up in the statement that we have gained an enormous insight into the anatomy of molecules, while our knowledge of their physiology is as yet in a rudimentary condition. In the course of the foregoing remarks I have endeavoured to indicate the direction in which our theoretical conceptions are most urgently pressing for extension. It is, perhaps, as yet premature to pronounce an opinion as to whether the next development is to be looked for from the stereochemical side; but it is not going too far to express once again the hope that the geometrical representation of valency will give us a deeper insight into the conditions which determine the stability of atomic configurations. The speculations of A. v. Baeyer, Wislicenus, Victor Meyer, Wunderlich, Bischoff, and others have certainly turned the attention of chemists towards a quarter from which a new light may eventually dawn.

THE PROGRESS OF SYNTHETICAL CHEMISTRY.

If, in my earnest desire to see the foundations of structural chemistry made more secure, I may have unwittingly given rise to the impression that I am depreciating its services as a scientific weapon, let me at once hasten to make amends by directing attention to the greatest of its triumphs, the synthesis of natural products, *i.e.* of compounds which are known to be produced by the vital processes of animals and plants.

Having been unable to find any recent list of the natural compounds which have been synthesised, I have compiled a set of tables which will, I hope, see the light at no very distant period. According to this census we have now realised about 180 such syntheses. The products of bacteria have been included in the list because these compounds are the results of vital activity in the same sense that alcohol is a product of the vital activity of the yeast plant. On the other hand the various uro-compounds resulting from the transformation in the animal economy of definite chemical substances administered for experimental purposes have been excluded, because I am confining my attention to natural products. Of course the importance of tracing the action of the living organism on compounds of known constitution from the physiological point of view cannot be overestimated. Such experiments will, without doubt, in time shed much light on the working of the vital laboratory.

The history of chemical synthesis has been so thoroughly dealt with from time to time that I should not have ventured to obtrude any further notice of this subject upon your patience were it not for a certain point which appeared to me of sufficient interest to merit reconsideration. It is generally stated that the formation of urea from ammonium cyanate by Wohler in 1828 was the first synthesis of an organic compound. There can be no doubt that this discovery, which attracted much attention at the time, gave a serious blow to the current conceptions of organic chemistry, because urea was so obviously a product of the living animal. It will be found, however, that about the same time Henry Hennell, of Apothecaries' Hall, had really effected the synthesis of alcohol—that is to say, had synthesised this compound in the same sense that Wohler had synthesised urea. The history is soon told. In 1826 Hennell (through Brande) communicated a paper to the Royal Society which appears in the *Philosophical Transactions* for that year.[1] In studying the compounds produced by the action of sulphuric acid on alcohol, and known as "oil of wine," he obtained sulphovinic acid, which had long been known, and gave fairly good analyses of this acid and of some of its salts, while expressing in the same paper very clear notions as to its chemical nature. Having satisfied himself that sulphovinic acid is a product of the action in question, he then proceeded to examine some sulphuric acid which had absorbed eighty times its volume of olefiant gas, and which had been placed at his disposal for this purpose by Michael Faraday. From this he also isolated sulphovinic acid. In another paper, communicated to the Royal Society in 1828,[2] he proves quantitatively that when sulphovinic acid is distilled with sulphuric acid and water the whole of the alcohol and sul-

[1] "On the Mutual Action of Sulphuric Acid and Alcohol, with Observations on the Composition and Properties of the resulting compound," *Phil. Trans.*, 1826, p. 240.

[2] "On the Mutual Action of Sulphuric Acid and Alcohol, and on the Nature of the Process by which Ether is formed," *Phil. Trans.*, 1828, p. 365.

phuric acid which united to form the sulphovinic acid are recovered. In the same paper he shows that he had very clear views as to the process of etherification. Hennell's work appears to have been somewhat dimmed by the brilliancy of his contemporaries who were labouring in the same field; but it is not too much to claim for him, after the lapse of nearly seventy years, the position of one of the pioneers of chemical synthesis. Of course in his time the synthesis was not complete, because he did not start from inorganic materials. The olefiant gas used by Faraday had been obtained from coal-gas or oil-gas. Moreover, in 1826-1828 alcohol was not generally regarded as a product of vital activity, and this is, no doubt, the reason why the discovery failed to produce the same excitement as the formation of urea. But the synthesis of alcohol from ethylene had, nevertheless, been accomplished, and this hydrocarbon occupied at that time precisely the same position as ammonium cyanate. The latter salt had not then been synthesised from inorganic materials, and the formation of urea, as Schorlemmer points out ("The Rise and Development of Organic Chemistry," p. 195), was also not a complete synthesis. The reputation of Wöhler, the illustrious friend and colleague of the more illustrious Liebig, will lose not a fraction of its brilliancy by the raising of this historical question. Science recognises no distinction of nationality, and the future historian of synthetical chemistry will not begrudge the small niche in the temple of fame to which Hennell is entitled.

Like many other great discoveries in science, the artificial formation of natural products began, as in the case of alcohol and urea, with observations arising from experiments not primarily directed to this end. It was not till the theory of chemical structure had risen to the rank of a scientific guide that the more complicated syntheses were rendered possible by more exact methods. We justly credit structural chemistry with these triumphant achievements. In arriving at such results any defects in the theory of structure are put out of consideration because—and this point must never be lost sight of—all doubt as to the possibility of this or that atomic grouping being stable is set aside at the outset by the actual occurrence of the compound in nature. The investigator starts with the best of all assurances. From the time of Wöhler and Hennell the course of discovery in this field has gone steadily on. The announcement of a new synthesis has ceased to produce that excitement which it did in the early days when the so-called "organic" compounds were regarded as products of a special vital force. The interest among the uninitiated now rises in proportion to the technical value of the compound. The present list of 180 odd synthetical products comprises, among the latest discoveries, gentisin, the colouring-matter of the gentian root (*Gentiana lutea*), which has been prepared by Kostanecki and Tambor, and caffeine, synthesised by Emil Fischer and Lorenz Ach, starting from dimethylurea and malonic acid.

I have allowed myself no time for those prophetic flights of the imagination which writers on this subject generally indulge in. When we know more about the structure of highly complex molecules, such as starch and albumin, we shall probably be able to synthesise these compounds. It seems to me more important just at present to come to an understanding as to what is meant by an organic synthesis. There appears to be an impression among many chemists that a synthesis is only effected when a compound is built up from simpler molecules. If the simpler molecules can be formed directly from their elements, then the synthesis is considered to be complete. Thus urea is a complete synthetical product, because we can make hydrogen cyanide from its elements; from this we can prepare a cyanate, and finally urea. In dictionaries and text-books we find synthetical processes generally separated from modes of formation, and the latter in their turn kept distinct from methods of preparation. The distinction between formation and preparation is obviously a good one, because the latter has a practical significance for the investigator. But the experience gained in drawing up the tables of synthesised compounds, to which I have referred, has resulted in the conclusion that the terms "synthesis" and "mode of formation" have been either unnecessarily confused or kept distinct without sufficient reason, and that it is impossible now to draw a hard-and-fast line between them. Some recent writers, such, for example, as Dr. Karl Elbs, in his admirable work on this subject ("Die synthetischen Darstellungsmethoden der Kohlenstoffverbindungen," Leipzig, 1889), have expanded the meaning of the word synthesis so as to comprise generally the building up of organic molecules by the combination of carbon with carbon, without reference to the circumstance whether the compound occurs as a natural product or not. But although this definition is sufficiently wide to cover the whole field of the production of carbon compounds from less complex molecules, it is in some respects too restricted, because it excludes such well-known cases as the formation of hydrogen cyanide from its elements, or of urea from ammonium cyanate. I should not consider the discussion of a mere question of terminology of sufficient importance to occupy the attention of this Section were it not for a matter of principle, and that a principle of the very greatest importance, which I believe to be associated with a clear conception of chemical synthesis. The great interest of all work in this field arises from our being able, by laboratory processes, to obtain compounds which are also manufactured in nature's laboratory—the living organism. It is in this direction that our science encroaches upon biology through physiology. Now, if we confine the notion of synthesis to the building up of molecules from simpler molecules or from atoms, we exclude one of nature's methods of producing many of these very compounds which we claim to have synthesised. There can be no manner of doubt that a large proportion, if not a majority, of the natural products which have been prepared artificially are not synthesised by the animal or plant in the sense of building up at all. They are the results of the breaking down—of the degradation—of complex molecules into simpler ones. I urge, therefore, that if in the laboratory we can arrive at one of these products by decomposing a more complex molecule by means of suitable reagents, we have a perfect right to call this a synthesis, provided always that the more complex molecule, which gives us our compound, can be in its turn synthesised, by no matter how many steps, from its constituent atoms. Thus oxalic acid has been directly synthesised from carbon dioxide by Kolbe and Drechsel by passing this gas over potassium or sodium amalgam heated to 360°. Whether the plant makes oxalic acid directly out of carbon dioxide we cannot at present state; if it does it certainly does not employ Kolbe and Drechsel's process. On the other hand this acid may, for all that is known, exist in the plant as a product of degradation. Many more complex acids, such as citric and tartaric, break down into oxalic acid when fused with potash. Both citric and tartaric acids can now be completely synthesised; therefore the formation of oxalic acid from these by potash fusion is a true synthesis.

The illustration given will make clear the point which I am urging. The distinction between a synthesis and a mode of formation vanishes when we can obtain a compound by the breaking down of a more complex molecule in all those cases where the latter can be completely built up. If we do not expand the meaning of synthesis so as to comprise such cases we are simply shutting the door in nature's face. It must be borne in mind that the actual yield of the compound furnished by the laboratory process does not come into consideration, because it may be generally asserted that in most cases the artifical processes are not the same as those which go on in the animal or plant. The information of real value to the physiologist which these syntheses give is the suggestion that such or such a compound may possibly result from the degradation of this or that antecedent compound, and not from a process of building up from simpler molecules.

The Bearing of Chemical Synthesis on Vital Chemistry.

With these views—the outcome of structural chemistry—the chemist and physiologist may join hands and move fearlessly onwards towards the great mystery of vital chemistry. In considering the results of organic synthesis two questions always arise as it were spontaneously: How does nature produce these complicated molecules without the use of strong reagents and at ordinary temperatures? What bearing have our laboratory achievements on the mechanism of vitality? The light shed upon these questions by experimental investigation has as yet flickered only in fitful gleams. We are but dwellers in the outer gates, waiting for the guide who is to show us the bearing of modern research on the great problem which confronts alike the physicist, the chemist, and the biologist. The chemical processes that go on in the living organism are complex to an extent that is difficult to realise. Of the various compounds of animal or vegetable origin that have been produced synthetically some are of the nature of waste products, resulting from metabolic degradation; others are the result of zymolytic action within the organism; and others, again, are secondary products arising from the action of associated bacteria, the relationship between the bac-

teria and their host being as yet imperfectly understood. The answer to the question how nature produces complicated organic molecules will be much facilitated when the physiologist, by experiment and observation, shall have made possible a sound classification of these synthetical products based on their mode of origination in the organism.

The enlargement of the definition of organic synthesis which I have advocated has been rendered necessary by the consideration of certain questions which have arisen in connection with the present condition of chemical discovery in this field. What evidence is there that any one of the 180 compounds which have been prepared artificially is produced in the organism by a direct process of building up? Is not the opposite view quite as probable? May they not, from the simplest to the most complex, be products of the degradation of still more complex molecules? I venture to suggest—not without some temerity lest our colleagues of Sections I and K should treat me as an intruder—that this view should be given a fair trial. I am aware that the opposite view, especially as regards plant assimilation, has long been held, and especially since 1870, when v. Baeyer advanced his celebrated theory of the formic aldehyde origin of carbohydrates. It is but natural to consider that the formation of a complex molecule is the result of a building-up process. It must be remembered, however, that in the living organism there is always present a compound or mixture, or whatever we like to call it, of a highly complex proteid nature, which, although at present indefinite from the purely chemical point of view, is the essence of the vitality. Of course I refer to what biologists have called protoplasm. Moreover, it is perhaps necessary to state what is really nothing more than a truism, viz. that protoplasm is present in and forms a part of the organism from the very beginning of its existence—from the germ to the adult, and onwards to the end of life. Any special chemical properties pertaining to protoplasm are inseparable from the animal or plant until that period arrives which Kekulé has hinted at when we shall be able to "build up the formative elements of living organisms" in the laboratory (NATURE, vol. xviii. p. 212). But here I am afraid I am allowing the imagination to take a flight which I told you a few minutes ago that time would not admit of.

The view that requires pushing forward into a more prominent position than it has hitherto occupied is that all the chemical transformations in the organism—at any rate all the primary changes—are made possible only by the antecedent combination of the substances concerned with living protoplasmic materials. The carbon dioxide, water, &c., which the plant absorbs must have formed a compound or compounds with the protoplasmic material of the chloroplasts before starch, or sugar, or cellulose can be prepared. There is, on this view, no such process as *the direct combination* of dead molecules to build up a complex substance. Everything must pass through the vital mill. The protoplasmic molecule is vastly more complex than any of the compounds which we have hitherto succeeded in synthesising. It might take up and form new and unstable compounds with carbon dioxide or formic aldehyde, or sugar, or anything else, and our present methods of investigation would fail to reveal the process. If this previous combination and, so to speak, vitalisation of dead matter actually occurs, the appearance of starch as the first visible product of assimilation, as taught by Sachs, or the formation of a 12-carbon-atom sugar as the first carbohydrate, as shown by the recent researches of Horace Brown and G. H. Morris, is no longer matter for wonderment. The chemical equations given in physiological works are too purely chemical; the physiologists have, I am afraid, credited the chemists with too much knowledge—it would appear as though their intimate familiarity with vital processes had led them to undervalue the importance of their prime agent. In giving expression to these thoughts I cannot but feel that I am treating you to the strange spectacle of a chemist pleading from the physiologists for a little more vitality in the chemical functions of living organisms. The future development of vital chemistry rests, however, with the chemist and physiologists conjointly; the isolation, identification, and analysis of the products of vital activity, which has hitherto been the task of the chemist, is only the preliminary work of physiological chemistry leading up to chemical physiology.

PROTOPLASMIC THEORY OF VITAL SYNTHESIS.

The supposition that chemical synthesis in the organism is the result of the combination of highly complex molecules with simpler molecules, and that the unstable compounds thus formed then undergo decomposition with the formation of new products, may be provisionally called the protoplasmic theory of vital synthesis. From this standpoint many of the prevailing doctrines will have to be inverted, and the formation of the more complex molecules will be considered to precede the synthesis of the less complex. It may be urged that this view simply throws back the process of vital synthesis one stage and leaves the question of the origin of the most complex molecules still unexplained. I grant this at once; but in doing so I am simply acknowledging that we have not yet solved the enigma of life. We are in precisely the same position as is the biologist with respect to abiogenesis, or the so-called "spontaneous generation." To avoid possible misconception let me here state that the protoplasmic theory in no way necessitates the assumption of a special "vital force." All that is claimed is a peculiar, and at present to us mysterious, power of forming high-grade chemical combinations with appropriate molecules. It is not altogether absurd to suppose that this power is a special property of nitrogen in certain forms of combination. The theory is but an extension of the views of Kuhne, Hoppe-Seyler, and others respecting the mode of action of enzymes. Neither is the view of the degradational origin of synthetical products in any way new.[1] I merely have thought it desirable to push it to its extreme limit in order that chemists may realise that there is a special chemistry of protoplasmic action, while the physiologists may exercise more caution in representing vital chemical transformations by equations which are in many cases purely hypothetical, or based on laboratory experiments which do not run parallel with the natural process. The chemical transformations which go on in the living organism are thus referred back to a peculiarity of protoplasmic matter, the explanation of which is bound up with the inner mechanism of the process of assimilation. If, as the protoplasmic theory implies, there must be combination of living protoplasm with appropriate compounds before synthesis is possible, then the problem resolves itself into a determination of the conditions which render such combination possible—*i.e.* the conditions of assimilation. It may be that here also light will come from the stereochemical hypothesis. The first step was taken when Pasteur found that organised ferments had the power of discriminating between physical isomerides; a similar selective power has been shown to reside in enzymes by the researches of Emil Fischer and his coadjutors. Fischer has quite recently expressed the view that the synthesis of sugars in the plant is preceded by the formation of a compound of carbon dioxide, or of formic aldehyde, with the protoplasmic material of the chloroplast, and similar views have been enunciated by Stohmann. The question has further been raised by van 't Hoff, as well as by Fischer, whether a stereochemical relationship between the living and dead compounds entering into combination is not an absolutely essential condition of all assimilation. The settlement of this question cannot but lead us onwards one stage towards the solution of the mystery that still surrounds the chemistry of the living organism.

RECENT DISCOVERIES OF GASEOUS ELEMENTS.

The past year has been such an eventful one in the way of startling discoveries that I must ask indulgence for trespassing a little further upon the time of the Section. It was only last year at the Oxford meeting of the British Association that Lord Rayleigh and Prof. Ramsay announced the discovery of a gaseous constituent of the atmosphere which had up to that time escaped detection. The complete justification of that announcement is now before the world in the paper recently published in the *Philosophical Transactions* of the Royal Society. The history of this brilliant piece of work is too recent to require much recapitulation. I need only remind you how, as the result of many years' patient determinations of the density of the gases oxygen and nitrogen, Lord Rayleigh established the fact that atmospheric nitrogen was heavier than nitrogen from chemical sources, and was then led to suspect the existence of a heavier gas in the atmosphere. He set to work to isolate this substance, and succeeded in doing so by the method of Cavendish. In the meantime Prof. Ramsay, quite independently, isolated the gas by removing the nitrogen by means of red-hot magnesium, and the

[1] See, *e.g.*, Vines' "Lectures on the Physiology of Plants," pp. 145, 218, 227, 233, and 234. Practically all the great classes of synthetical products are regarded as the results of the destructive metabolism of protoplasm. A special plea for protoplasmic action has also been urged, from the biological side, by W. T. Thiselton-Dyer, *Journ. Chem. Soc.*, 1893; *Trans.* pp. 680-681

two investigators then combining their labours, followed up the subject, and have given us a memoir which will go down to posterity among the greatest achievements of an age renowned for its scientific activity.

The case in favour of argon being an element seems to be now settled by the discovery that the molecule of the gas is monatomic, as well as by the distinctness of its electric spark spectrum. The suggestion put forward soon after the discovery was announced, that the gas was an oxide of nitrogen, must have been made in complete ignorance of the methods by which it was prepared. The possibility of its being N_3 has been considered by the discoverers and rejected on very good grounds. Moreover, Peratoner and Oddo have been recently making some experiments in the laboratory of the University of Palermo with the object of examining the products of the electrolysis of hydrazoic acid and its salts. They obtained only ordinary nitrogen, not argon, and have come to the conclusion that the anhydride $N_3.N_3$ is incapable of existence, and that no allotropic form of nitrogen is given off. It has been urged that the physical evidence in support of the monatomic nature of the argon molecule, viz. the ratio of the specific heats, is capable of another interpretation—that argon is in fact an element of such extraordinary energy that its atoms cannot be separated, but are bound together as a rigid system which transmits the vibrational energy of a sound-wave as motion of translation only. If this be the state of affairs we must look to the physicists for more light. So far as chemistry is concerned, this conception introduces an entirely new set of ideas, and raises the question of the monatomic character of the mercury molecule which is in the same category with respect to the physical evidence. It seems unreasonable to invoke a special power of atomic linkage to explain the monatomic character of argon, and to refuse such a power in the case of other monatomic molecules, like mercury or cadmium. The chemical inertness of argon has been referred also to this same power of self-combination of its atoms. If this explanation be adopted it carries with it the admission that those elements of which the atoms composing the molecule are the more easily dissociated should be the more chemically active. The reverse appears to be the case if we bear in mind Victor Meyer's researches on the dissociation of the halogens, which prove that under the influence of heat the least active element, iodine, is the most easily dissociated. On the whole, the attempts to make out that argon is polyatomic by such forced hypotheses cannot at present be considered to have been successful, and the contention of the discoverers that its molecule is monatomic must be accepted as established.

In searching for a natural source of combined argon Prof. Ramsay was led to examine the gases contained in certain uranium and other minerals, and by steps which are now well known he has been able to isolate helium, a gas which was discovered by means of the spectroscope in the solar chromosphere during the eclipse of 1868 by Profs. Norman Lockyer and E. Frankland. In his address to the British Association in 1872 (*Reports*, 1872, p. lxxiv. the late Dr. W. B. Carpenter said:—

"But when Frankland and Lockyer, seeing in the spectrum of the yellow solar prominences a certain bright line not identifiable with that of any known terrestrial flame, attribute this to a hypothetical new substance which they propose to call helium, it is obvious that their assumption rests on a far less secure foundation, until it shall have received that verification which, in the case of Mr. Crookes' researches on thallium, was afforded by the actual discovery of the new metal, whose presence had been indicated to him by a line in the spectrum not attributable to any substance then known."

It must be as gratifying to Profs. Lockyer and Frankland as it is to the chemical world at large to know that helium may now be removed from the category of solar myths and enrolled among the elements of terrestrial matter. The sources, mode of isolation, and properties of this gas have been described in the paper recently published by Prof. Ramsay and his colleagues. Not the least interesting fact is the occurrence of helium and argon in meteoric iron from Virginia, as announced by Prof. Ramsay in July (NATURE, vol. lii. p. 224). Like argon, helium is monatomic and chemically inert so far as the present evidence goes. The conditions under which this element exists in cleveite, uraninite, and the other minerals have yet to be determined.

Taking a general survey of the results thus far obtained, it seems that two representatives of a new group of monatomic elements characterised by chemical inertness have been brought to light. Their inertness obviously interposes great difficulties in the way of their further study from the chemical side: the future development of our knowledge of these elements may be looked for from the physicist and spectroscopist. Prof. Ramsay has not yet succeeded in effecting a combination between argon or helium and any of the other chemical elements. M. Moissan finds that fluorine is without action on argon. M. Berthelot claims to have brought about a combination of argon with carbon disulphide and mercury, and with "the elements of benzene, . . . with the help of mercury," under the influence of the silent electric discharge. Some experiments which I made last spring with Mr. R. J. Strutt with argon and moist acetylene submitted to the electric discharge, both silent and disruptive, gave very little hope of a combination between argon and carbon being possible by this means. The coincidence of the helium yellow line with the D_3 line of the solar chromosphere has been challenged, but the recent accurate measurements of the wave-length of the chromospheric line by Prof. G. E. Hale, and of the line of terrestrial helium by Mr. Crookes, leave no doubt as to their identity. Both the solar and terrestrial lines have now been shown to be double. The isolation of helium has not only furnished another link proving community of matter, and, by inference, of origin between the earth and sun, but an extension of the work by Prof. Norman Lockyer, M. Deslandres, and Mr. Crookes, has resulted in the most interesting discovery that a large number of the lines in the chromospheric spectrum, as well as in certain stellar spectra, which had up to the present time found no counterparts in the spectra of terrestrial elements, can now be accounted for by the spectra of gases contained with helium in these rare minerals. The question now confronts us, Are these gases members of the same monatomic inert group as argon and helium? Whether, and by what mechanism, a monatomic gas can give a complicated spectrum is a physical question of supreme interest to chemists, and I hope that a discussion of this subject with our colleagues of Section A will be held during the present meeting. That mercury is capable under different conditions of giving a series of highly complex spectra can be seen from the memoir by J. M. Eder and E. Valenta, presented to the Imperial Academy of Sciences of Vienna in July 1894. With respect to the position of argon and helium in the periodic system of chemical elements, it is, as Prof. Ramsay points out, premature to speculate until we are quite sure that these gases are homogeneous. It is possible that they may be mixtures of monatomic gases, and in fact the spectroscope has already given an indication that they contain some constituent in common. The question whether these gases are mixtures or not presses for an immediate answer. I will venture to suggest that an attack should be made by the method of diffusion. If argon or helium were allowed to diffuse fractionally through a long porous plug into an exhausted vessel there might be some separation into gases of different densities, and showing modifications in their spectra, on the assumption that we are dealing with mixtures composed of molecules of different weights.

NOTES.

THE *Times* of Tuesday last contained a letter, signed by Profs. M. Foster, E. Ray Lankester, and G. B. Howes (Hon. Secretaries to the Provisional Committee), with reference to the General Committee now being formed for the purpose of establishing a memorial of the late Prof. Huxley. The letter states that H.R.H. the Prince of Wales has been pleased to become the Honorary President of the Committee. No very active steps can be taken until after the autumn recess, when the General Committee will hold its first meeting, probably in October. The Honorary Secretaries will after that report the progress that has been made both in this country and abroad, and a list of the complete Committee and a statement of the subscriptions received will be published. Appended to the letter is a list of an enormous number of names of persons who have already signified their desire to serve on the Committee.

A MEMORIAL tablet in honour of Prof. Helmholtz has been affixed to the house, No. 8 Hadtzstrasse, at Potsdam, where he was born, and it is stated that it is intended to erect a joint

monument to the memory of Werner Siemens and Helmholtz in front of the Technische Hochschule at Charlottenburg.

Prof. Retsius and Dr. Bergh, of Copenhagen, have been elected Correspondants of the Paris Academy.

The Berliner Akademie der Wissenschaften has, we understand, recently elected the following gentlemen as corresponding members:—Prof. W. V. Gümbel (Münich), Prof. A. von Zittell (Münich), Prof. A. Schrauf (Vienna), Prof. A. Cossa (Turin), Prof. A. Agassiz (Cambridge, Mass.), and Prof. E. Mascart (Paris).

The quinquennial International Metric Congress, which is at present being held in Paris, under the presidency of Dr. Marey, was opened on the 4th inst. by M. Hanotaux, who delivered a brief address. On the 6th inst. the second session of the Congress took place, and M. Hirsch, of the Neuchâtel Observatory, was elected Secretary. The Secretary presented the report of the Committee on the work already done, and the present state of the International Bureau of Weights and Measures, and a series of metric standards which have been under consideration since the Congress of 1889 was sanctioned.

The Swiss Naturforschende Gesellschaft has been holding its annual congress at Zermatt. The proceedings began on September 8, and concluded on the 11th. September 8 was devoted to the meetings of committees; the Sections met on September 10, and on the 9th and 11th inst. the general meetings took place.

The death is announced of Dr. Sven Lovén, the distinguished Swedish naturalist. He was born, says the *Times*, at Stockholm in 1809, and received his education at the University of Lund, where he took the degree of Doctor of Philosophy. After attending lectures in Berlin in 1830-31, he devoted himself to the study of the maritime fauna of the coasts of Scandinavia. He also explored the Baltic and the North Seas, and conducted the first scientific expedition to Spitzbergen in 1837. He was the author of numerous scientific memoirs, all published by the Royal Swedish Academy of Sciences. Dr. Lovén was elected a member of the Academy of Stockholm in 1840, and Professor and Conservator of the Royal Museum of Natural History of that city in 1841. He was a member of the academies of Berlin and Munich, a corresponding member of the Institute of France, and in 1885 was elected a foreign member of the Royal Society of London.

The death is recorded, at the age of eighty-one years, of Mr. James Carter, of Cambridge. For very many years Mr. Carter practised as a medical man, but found time to engage in the study of scientific and antiquarian subjects, and was especially interested in palæontology. He contributed many papers to the *Geological Magazine* and the *Quarterly Journal* of the Geological Society, and served for many years on the Councils of the Geological and Palæontological Societies.

The *Kew Bulletin* has heard with regret of the death from dysentery in May last of Mr. F. H. Smiles, who had been attached to the Royal Survey Department of Siam. Mr. Smiles, who had already done some good botanical work, returned to Siam in December last with the intention of making further botanical collections, and it was confidently anticipated that he would have added considerably to the knowledge of the rich flora of Upper Siam.

The death is announced of Mr. R. H. Tweddell, the well-known engineer; of Mr. E. F. C. Davis, president of the American Society of Mechanical Engineers; and of Mr. H. C. Hart, one of the first class technical officers of the engineer-in-chief's office, Post Office Telegraphs.

The centenary of Jenner's first experiments in vaccination is to be celebrated next May by the Russian National Health Society. To commemorate the event the Society proposes (1) to offer four prizes for the best works upon vaccination; (2) to collect and publish materials for a history of the practice of vaccination in Russia, and a short history of the same in Western Europe; (3) to publish a Russian translation of Jenner's works, accompanied by his biography and portrait; (4) to organise an exhibition of objects connected with vaccination; (5) to hold a commemorative meeting on the day of the centenary.

The annual joint meeting of the Swiss Geographical Societies will be held this year at St. Gall, on September 22 and 23. At this meeting a paper will be read by Dr. Hans Meyer on the "Snow Mountains of Equatorial Africa."

An exhibition of agricultural machinery, similar to that held in May of the present year, is being arranged under the auspices of the Imperial and Royal Agricultural Society of Vienna, to take place in that city in May 1896. The exhibits will comprise not only agricultural machines as generally understood, but appliances used in all branches of industry connected with agriculture, such as breweries, and distilleries, and yeast, sugar, vinegar, and starch factories.

We learn from the *Nation*, New York, that only one MS. was received in competition for the prize of 400 dollars given by Dr. Gould's *Astronomical Journal* "for the most thorough discussion of the theory of the rotation of the earth with reference to the recently discovered variations of latitude." The paper was sent by and the prize awarded to Prof. Newcomb. The other prize, of 200 dollars, was given to Mr. Paul S. Yendell, for the best series of determinations of maxima and minima of variable stars.

Science states that the Berliner Akademie der Wissenschaften has recently put aside over £1000 for the promotion of scientific work and research. Of this amount an appropriation of £100 has been made to Prof. Fuchs, of Berlin, to be devoted to the continuation of the publication of Dirichlet's works; £100 to Prof. Weierstrass, of Berlin, for the publication of his collected works; £75 to Prof. Gerhardt for the publication of the mathematical correspondence of Leibnitz, and £100 to Dr. Schauinsland for researches on the Fauna of the Pacific islands.

The Göttingen Gesellschaft der Wissenschaften will, on February 1, 1897, award a prize of 500 marks for an anatomical research and description of the cavities of the body of the new-born child and their contents compared with those of the adult.

The Academy of Sciences of Cracow proposes, as the subject for the Copernicus prizes, theories concerning the physical condition of the globe. Essays must be written in the Polish language, and reach the Academy before the end of 1898.

The Orient Steam Navigation Company, Limited, announce their intention of sending one of their steamships to Vadsö, Varanger Fiord, Lapland, in August next, to enable observations to be made of the total eclipse of the sun on August 9, 1896. It is arranged for the vessel to leave London on July 21, to arrive at Vadsö on August 3, and to return from the latter place on the 10th, reaching London on August 17. Particulars as to the cost, &c., of the trip may be seen in our advertisement columns, or obtained from Messrs. Anderson, Anderson, and Co., 5 Fenchurch Avenue, E.C., or 16 Cockspur Street, S.W.

Severe thunderstorms again occurred in the southern and eastern parts of England early on Saturday morning, 7th instant, accompanied with heavy falls of hail and rain, and causing considerable damage. The disturbance was occasioned by the

development of shallow depressions over the Bay of Biscay and the English Channel, and by the intense heat over the continent, the maximum shade temperature in some parts of France being considerably above 90°, while in the east of England a temperature of 85° was recorded. Rainfall exceeded an inch in London and other places, and amounted to 1·78 inches in Hampshire. During the height of the storm the lightning flashes averaged about twenty-five to the minute.

THE Shetland County Council, says the *Glasgow Herald*, has resolved to apply to the Secretary for Scotland for an order under the Wild Birds Protection Act of 1894, prohibiting the taking of the eggs of certain wild birds. The schedule proposed includes such birds as the white-tailed or sea eagle, great skua, Richardson's skua, Allan whimbrel, ember goose, &c. All these birds have become extremely rare, and it is stated that there has been recently a trade carrying on in their eggs for the American market, to the threatened extinction of the birds.

WE are asked to announce that with the September number the *American Journal of Psychology* will enter upon its seventh volume. The preceding volumes have been edited by President G. Stanley Hall (Clark University). For the future the editorial responsibility of the *Journal* will be shared by President Hall, Prof. E. C. Sanford (Clark University), and Prof. E. B. Titchener (Cornell University). A co-operative board has been formed, which includes the names of Prof. F. Angell, Prof. H. Beaunis, Prof. J. Delboeuf, Dr. A. Kirschmann, Prof. O. Kuelpe, Dr. A. Waller, F.R.S., and Prof. H. K. Wolfe. The *Journal* will be devoted exclusively to the interests of experimental psychology (psychophysiology, psychophysics, physiological psychology, &c.). Each number will contain, as heretofore, original articles, reviews and abstracts of current psychological books and monographs, and notes upon topics of immediate psychological importance. Contributions may be addressed to either of the three editors.

Science states that the Board of Scientific Directors of the New York Botanic Garden has recently resolved to authorise a topographical survey of the 250 acres of land in Bronx Park which have been set aside for the uses of the garden. All the trees in the park are to be labelled, and new varieties of seeds desirable for cultivation are to be secured.

THE Allahabad *Pioneer Mail* says that an experiment is now in progress in several of the larger gaols of the Punjab, which may have important results in the future. It has been one of the ordinary precautions in time of cholera epidemics to boil the drinking water supplied to the prisoners. To ascertain whether it might not be advisable always to boil the drinking water, the Lieutenant-Governor has ordered that a certain number of the prisoners should be given boiled, and an equal number unboiled, water, the results being reported at the end of the year. If these are as expected, the reduction in the fever death-rate should be followed by a similar reduction in the mortality from dysentery and diarrhoea.

WE learn from *Engineering* that an important undertaking has been inaugurated at Seattle, in the State of Washington, U.S.A. This city is situated on Elliott Bay, a thoroughly sheltered harbour, which communicates with the Pacific by the Straits of San Juan de Fuca. About two miles from the coast and behind the town is a fresh-water lake of considerable size, the water level of which is about 16 feet above high water in the bay. A ship canal between the lake and the sea has long been suggested, and the work has at last been definitely commenced. The bottom of the channel will be 80 feet, and the greatest depth of cutting will be 308 feet. Almost the whole of the work will, however, be carried out through comparatively high land, the amount of excavation required being estimated at 36,000,000 cubic yards. The material is mostly glacial drift, and it is proposed to use hydraulic nozzles to facilitate the work of excavation, the spoil being washed down by a jet of water issuing at high pressure from a nozzle, as in some of the Californian gold workings. A lock 400 feet long will be constructed at the sea entrance to the canal. The material excavated will be used for raising the level of low-lying ground along the sea front of the city.

M. ZACHAREWIEZ, Professor of Agriculture at Vaucluse, has found by experiment with different-coloured glasses that fruit is finest and earliest when grown under clear glass. Orange glass produces an increase of vegetation, but at the cost of the amount of fruit, of the size and of its forwardness. Violet glass causes the number of fruit to increase at the expense of the quality. Red, blue, and green glass are hurtful to all kinds of vegetation.

THE possibility of successfully boring for water in extensive areas of crystalline rocks has been demonstrated, we learn from the September number of *Natural Science*, at several places in Sweden. The experiments were suggested by certain conclusions of Nordenskiöld, based on the downward limit of surface variations of temperature and other physical considerations. He considered that vertical jointing of the rocks would not extend below 30 or 40 metres, and that at that depth extensive horizontal fissures must be formed. This has now been found to be the case, and from these horizontal fissures abundant water of great purity has been obtained. While these results are of practical importance (particularly with regard to the water-supply of small rocky islands), it also opens up a number of interesting general questions as to the flow and pressure of water in crystalline rocks.

IN our issue for August 15, we printed an abstract of a paper on "The Voyage of the *Antarctic* to Victoria Land," read by Mr. C. E. Borchgrevink at the recent International Geographical Congress, and now have to acknowledge the receipt of the journal and notes of the commander of the whaler *Antarctic*, in which Mr. Borchgrevink made his somewhat unpropitious voyage as a sailor before the mast, which the Secretary of the Royal Geographical Society of Australasia (Victorian Branch) has been good enough to send us. The pamphlet, which contains some highly interesting matter, is accompanied by a lithographed map, by Captain Leonard Kristensen, of the track taken by his vessel, and forms part of the *Transactions* of the above-named Society.

Natural Science for September contains extracts from the address delivered by the Rev. Canon A. M. Norman, F.R.S., as President of the recently held Museums Association at Newcastle, and deals with the progress of biology in that northern town. An article on "The Geology of Ipswich and its Neighbourhood," by Mr. Clement Reid, appears at an opportune moment, and will doubtless be consulted by many geologists visiting the British Association. Other contributions to the number are:—"Some Recent Insect Literature," "The Nucleolus," "The Rôle of Sex," and "The Alleged Miocene Man in Burma." The last-named article has reference to a paper by Dr. Noetling, published towards the close of last year, "On the Occurrence of Chipped (?) Flints in the Upper Miocene of Burma." The writer, Mr. R. D. Oldham, says in conclusion, "till more complete evidence has been produced it is impossible to accept the existence of man in either Miocene or Pliocene times as one of the established facts of geology."

WE are glad to note the reappearance of the *Bollettino Mensuale* of the reorganised Italian Meteorological Society. The bulletin is issued in a more convenient, small folio form, but in other respects it is similar to the former publication. The current number contains two important articles by Prof. L. Di Marchi, on the causes of the glacial epoch, and the dynamical

conditions of thunderstorms, and an investigation of the effects of the earthquake at Florence on May 18 last, by C. Bassani.

AN examination of the gases liberated from certain of the sulphurous waters of the Pyrenees reveals, in the hands of M. Ch. Bouchard, the interesting fact that the formerly assumed nitrogen (from which the Spanish physicians have named these waters *azoades*) consists in part of free argon and helium. The collected gas was in each case, after treatment with potash and phosphoric anhydride, introduced into a Plücker tube containing magnesium wire. Under the action of the silent discharge the nitrogen rapidly disappeared by combination with magnesium, leaving a residue exhibiting the characteristic rays of both argon and helium for the gas derived from the waters of la Raillère, helium from the springs of Bois, and helium together with probably an unknown gas from the waters of lowest temperature at Bois.

THE use of magnesium wire and the silent discharge is due to MM. L. Troost and L. Ouvrard, who show that the magnesium vapour produced very rapidly combines with nitrogen under the conditions obtaining in the tubes. Further, the continued action of a powerful silent discharge, for some hours after the spectroscopic evidence proves the absence of nitrogen, results in a gradual diminution in intensity of the helium and argon rays. Finally a complete vacuum is produced, hence it appears that magnesium combines with argon and helium under these circumstances. Platinum appears to behave like magnesium towards argon in Plücker tubes with the silent discharge.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mrs. Ball; an Emu (*Dromaeus novae-hollandiae*) from Australia, presented by Mr. C. W. Williams; a Raven (*Corvus corax*), British, presented by Mr. W. Weeker; a Royal Python (*Python reginis*) from Dahomey, West Africa, presented by Mr. C. H. Harley-Moseley; a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. C. Sampson; a —— Snake (*Phrynonax eutropis*), a —— Snake (*Phrynonax fasciatus*) from Trinidad, presented by Mr. R. R. Mole; a White-tailed Sea Eagle (*Haliaetus albicilla*) from Scotland, two Diamond Snakes (*Morelia spilotes*) from Australia, deposited; eight Amherst Pheasants (*Thaumalea amherstiae*), six Ring-necked Pheasants (*Phasianus torquatus*), two Japanese Pheasants (*Phasianus versicolor*), a Temminck's Tragopan (*Ceriornis temmincki*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE PROPER MOTION OF THE SUN. In the September number of the *Bulletin Astronomique* M. Tisserand gives an interesting account of a method of determining the proper motion of the sun from stellar proper motions. Denoting by m and m' the values of the annual proper motions of the stars, c the space described by the sun in one year, this space being measured with the same unit as the distance (ρ) of the sun, and A and D the Right Ascension and Declination of the apex of the sun's way, the formulae for reduction become

$$m \cos \delta = \frac{c}{\rho} \cos \mathrm{D} \sin (\alpha - \mathrm{A})$$

$$\frac{m'}{\cos \delta} = -\frac{c}{\rho} \sin \mathrm{D} + \frac{c}{\rho} \cos \mathrm{D} \tan \delta \,.\, \cos (\alpha - \mathrm{A}).$$

In the second equation the second term changes its sign with $\tan \delta$, ρ changes its value from star to star. Assuming that the mean of the values of this term will be small or zero, and that Σ represents the arithmetical mean, we have—

$$\Sigma\left(\frac{m'}{\cos \delta}\right) = -c \sin \mathrm{D}\, \Sigma\left(\frac{1}{\rho}\right).$$

Now, because sin D is positive, the mean values of the left-hand side of the equation ought to be negative. If there were no proper motion to the sun, they should be zero.

Using the catalogue of 1054 stellar proper motions, motions of M. Stumpe (*Astr. Nach.*, Nos. 2999-3000, year 1890), only those stars have been employed the declinations of which are comprised between $-30°$ and $+30°$, and the proper motions less than $0''\cdot64$.

The mean values for the sum above were then tabulated for every hour of Right Ascension. These were found to be all negative, as they ought to be, and they did not differ very much from one another. For 585 stars the mean value was $-0''\cdot151$.

M. Tisserand further investigated the values obtained from another catalogue of 2641 stellar proper motions, by M. Bossert, in exactly the same way. Here the mean values were still found all to be negative, and not very different from one another. From 1537 proper motions the value obtained was $-0''\cdot131$.

By taking only the proper motions of stars comprised between declinations $\pm 15°$, the value obtained does not differ materially from that given above. In the interval then of a century, for each hour of right ascension, the declinations of all the stars have diminished (in the mean) by quantities comprised between $10''$ and $20''$; and he says, "il nous semble que cela donne une preuve materielle frappante du mouvement du Soleil."

THE ROTATION OF VENUS.—A difficult problem in observational astronomy is the determination of the period of the rotation of Venus. M. Schiaparelli, whose powers of observations have been often put to the test, still thinks that the planet accomplishes one rotation in the same time that it takes to travel round the sun, or, in other words, the same hemisphere is always turned towards the sun. M. Leo Brunner, however, who has made during three months a great number of drawings, which appear to corroborate his statement, seems to be of quite a different opinion, for he says: "J'ai le plaisir de vous annoncer que je viens de découvrir la vraie période de rotation de Venus, qui ne diffère que de quelques minutes de celle de notre terre. Cette découverte est hors doute, car j'ai pu voir arriver et passer des taches plusieurs jours avec la plus grande distinction. Nul doute à cet egard." It must not be forgotten, however, that the observation of Venus is one attended by great difficulty. Even Brunner's drawings and those of Schiaparelli made of the planet at the same time are very different. There seems to be no doubt that the observations are all verging on the limit of visibility, and that the 224 days or the 24-hour period are just as probable as ever.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following appointments have been recently made by the governing bodies of the undermentioned colleges:—At St. John's, Mr. R. H. Adie, a Lecturer in Natural Science; at Magdalene, Mr. G. T. Manley, Lecturer in Mathematics; at Trinity, Mr. G. T. Walker, Lecturer in Mathematics, and Messrs. W. C. D. Whetham and J. W. Capstick, Lecturers in Nataral Science; at Emmanuel, Mr. A. Eicholz, Lecturer in Natural Science; at Sidney Sussex, Mr. R. H. D. Mayall, Lecturer in Mathematics; at Selwyn, Mr. L. A. Borradaile, Lecturer in Natural Science.

ACCORDING to *Science*, Prof. Bonnet, Professor of Anatomy in the University of Giessen, has received a call to Greifswald; and Dr. M. Miyoshi has been appointed Professor of Botany in the University of Tokyo.

MR. CHAS. BERRY, horticultural lecturer to the East Suffolk County Council Technical Instruction Committee, has been appointed Instructor in Horticulture by the Devonshire County Council, and will enter upon his duties at the end of September.

THE prospectus of Day and Evening Classes at the Battersea Polytechnic Institute for the session 1895-6, has reached us, and contains full information respecting the numerous classes held at this well-appointed institution. Several new classes are to be formed, and special provision is made for the needs of students who are desirous of entering for the examination of London University, from the matriculation to the final B.Sc.

THE fourth annual report (1894-5) of the Department of Agriculture, Yorkshire College, Leeds, has been published, and shows clearly that a great deal of useful work has been carried on during the past twelve months, and has, on the whole, met with very satisfactory success. With one exception (that of the classes for elementary teachers) each branch has exhibited much growth. The lectures given to farmers and others were

well attended, and the work of the lecturers was much assisted by the travelling libraries sent out by the Victoria University in connection with the various courses. A new departure was made by the institution of short lectures on poultry-keeping. At the close of the session examinations were held, at which 188 candidates from 26 centres presented themselves, and of this number 145 passed, 58 attaining distinction. The prospectus of the Courses in Agriculture, Session 1895-6, is now ready, and may be had on application to the Registrar.

THE Agricultural Department of the University College of North Wales, Bangor, has just issued its prospectus for the approaching session, in which all information respecting classes, &c., is given. Arrangements have been made by which farms in the neighbourhood of the college may be made use of by the professors and their students for practical instruction. The prospectus can be obtained from the Secretary.

THE *Technical World* says: "One of the most interesting experiments undertaken by the Durham College of Science is the provision of a series of agricultural stations, of which there are now about sixty in Northumberland, Cumberland, and Durham. At these stations practical instruction is given by means of experiment and demonstration in the science of agriculture. Manures are supplied to the stations from the college, where they are analysed and blended as may be required for the particular experiment, and the resultant crops are afterwards tested under the direction of the Professor of Agriculture. These experiments give valuable opportunities to students to observe the varying results obtained under the different conditions of soil and climate in the various districts of the North, and also provide useful data for agriculturists therein."

A NEW technical school was opened at Runcorn on August 31, by Sir John T. Brunner, M.P. The school was erected at a cost of £4200, and contains eleven class-rooms and a lecture-hall.

IN view of the forthcoming opening of the Medical Schools, the current issues of our contemporaries, the *Lancet* and *British Medical Journal*, are devoted almost exclusively to particulars likely to be of service to medical students. The *Chemical News* for September 6 is likewise a "student's number," and contains much information respecting the various schools of chemistry.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 2.—M. Fizeau in the chair.—The work of 1895 at Mont Blanc Observatory, by M. J. Janssen. Determinations of the intensity of gravity have been made with very delicate instruments at Grands-Mulets (3050 m.) and at Chamounix by M. Bigourdan. It is hoped to carry out a similar determination on the summit of Mont Blanc next year. All the parts of the 33 cm. parallactic telescope have been conveyed to the site at the head of the glacier where it is to be erected.—On the presence of argon and of helium in certain mineral waters, by M. Ch. Bouchard. (See Notes, p. 487).—On the combination of magnesium with argon and with helium, by MM. L. Troost and L. Ouvrard. (See Notes, p. 487).—On a continuous group of transformations with twenty-eight parameters which occurs in the theory of deformation of surfaces, by M. Paul Staeckel.—Researches on the combinations of mercuric cyanide with bromides, by M. Raoul Varet. Thermochemical data are given for a number of compounds of the general type $2HgCy_2.MBr_2.xH_2O$. It is shown that in solution these substances yield but a slight isopurpurate reaction, and slightly redden litmus. With heat the effect is increased. The substances possess a similar constitution as the chlorocyanides, the cyanogen remaining mostly in combination with the mercury. Rather a greater proportion of the cyanogen passes over to the second metal than in the case of the chlorocyanides. A slight evolution of heat occurs in the change, a result contrary to what would be expected from the character of the iodo-compounds.—On the formation of hydrogen selenide, by M. H. Pelabon. Liquid selenium absorbs hydrogen selenide. Carrying out experiments on the formation of hydrogen selenide in relation to temperature with the smallest excess of selenium in order to avoid this source of error, it is found that the formula of Gibbs and Duhem,

$$\log \frac{p_1}{p_2} = \frac{M}{T} + N \log T + S,$$

accurately represents the experimental results (p_1 and p_2 represent the partial pressures of H and SeH_2, T is the abs. temp. of experiment, log means Napierian log, M, N, and S are constants). The ratio $\rho = \frac{p_2}{p_1 + p_2}$ has a maximum value at a temperature $t = \frac{M}{N} - 273$. With values of the constants calculated from the experimental results, $t = 575°$, the experimental maximum agrees with this result. The molecular heat of formation calculated by Duhem's formula with the found values for the above constants is − 17380 Cal., Fabre found − 18000 Cal. The difference is not great, and may be readily accounted for when it is remembered that (1) in this formula hydrogen and hydrogen selenide have been assumed to be perfect gases; (2) the formula has been applied beyond the limits of temperature of the experiments from which M and N are determined.—Action of carbonic acid, water, and alkalis on cyanuric acid and its dissolved sodium and potassium salts, by M. Paul Lemoult. A heat of neutralisation paper in which the decomposition of cyanuric acid slowly occurring in presence of bases is shown to agree with the equation $C_3N_3O_3H_3$ diss. + $3H_2O$ + Aq = $3CO_2$ diss. + $3NH_3$ diss. + 200 Cal.—The eclipsoscope, an apparatus for viewing the chromosphere and solar protuberances, by M. Ch. V. Zenger.—M. Ch. V. Zenger sends another note relative to the possibility of predicting great seismic and atmospheric disturbances during the passage of periodic swarms of shooting-stars when great activity of the solar surface is observed at the same time.

THURSDAY, SEPTEMBER 19, 1895.

THE BRITISH ASSOCIATION.

WEDNESDAY.

THE British Association meeting at Ipswich has now practically come to an end. The stream of strangers which set towards the town a week ago shows signs of retiring, and, in the course of a day or two, the ancient and interesting county town of Suffolk will have returned to its normal condition. The meeting has been a very pleasant one for all, and the delightful weather of the past week has naturally attracted a large attendance at each of the many enjoyable excursions to places of interest in the surrounding country. The Association has often met in places far richer in educational and scientific institutions than Ipswich, but it has rarely met in a centre within easy reach of picturesque scenery offering more facilities for geological observation, or possessing a greater abundance of objects of interest to students of antiquities. This, combined with the fact that papers of extreme value have been communicated to each of the Sections, will make the meeting memorable to all who have attended it. As we shall follow our usual custom of giving reports of the work done in the Sections, it is unnecessary here to do more than refer to one or two of the papers and discussions which have excited general interest.

The subject of scientific research was brought up in Section A by Sir Douglas Galton's description of the Reichanstalt, Charlottenburg. After giving a full account of the construction, endowment, and management of that institution, which has for its object "the development of pure scientific research and the promotion of new applications of science for industrial purposes," it was pointed out that, in this country, there is no Government department which approximates to it. Recognising our deficiency in this respect, the suggestion was made that a committee of inquiry take the matter up, with the idea of formulating some definite proposal for the establishment of a central institution where standardising and research could be carried on without interruption. If the ideas with reference to such an institution should take tangible shape, as we sincerely hope they will, the Ipswich meeting will be remarkable in the annals of the Association as one from which a new departure in national enterprise began.

The joint meeting of Sections A and B, on Friday, was marked by two important communications on argon and helium. By methods which command the admiration of every one who can appreciate scientific inquiry, Lord Rayleigh showed how he had measured the refraction and viscosity of the two new gases. The refractive index of argon turns out to be 0·961, while that of helium appears to be as low as 0·146; both being compared with dry air. With the viscosity of dry air as the standard of comparison, those of argon and helium were respectively 1·21 and 0·96. Another interesting matter referred to by Lord Rayleigh in the course of his communication was the nature of the gas from the mineral spring at Bath. Some months ago, before the discovery of terrestrial helium, Lord Rayleigh and Prof. Ramsay examined samples of that gas for argon, but without finding the new element. The results were such, however, that an examination of the gas for helium was lately undertaken, and Lord Rayleigh was able to say that he had proved spectroscopically that helium really exists in the Bath gas. The question as to the nature of helium itself was elucidated by Prof. Runge in his contribution to the discussion of "the evidence to be gathered as to the simple or compound character of a gas from the constitution of its spectrum." It may be remembered that a short time ago, Prof. Runge contributed to these columns an article on the analysis of spectra by investigation of the periodic distribution of wave-lengths. He took the spectrum of lithium as a typical example of a spectrum which could be resolved into two spectra, the lines in each of which were connected by a simple formula. Taking his own observations of the spectrum of helium, Prof. Runge showed that helium is not an element but consists of two, and not more than two, elements. The conclusion is arrived at because the helium spectrum can be resolved into two sets of lines each apparently distinct from the other.

Of all the Sections, those of Geography and Anthropology have attracted the largest attendance, owing doubtless to the fact that the subjects dealt with could be easily followed, and are of general interest. But, besides the more or less popular papers of a resurrectionary character, a large number of distinctly new subjects have been brought up and discussed. The difficulty has been to find time for the long lists published in each day's *Journal*, and this difficulty is increased by the apparent inability of some of the readers of papers to express their conclusions in concise language. On account of the lack of this quality, the time for discussions has in several cases been very limited, and thus the first aim of a meeting of scientific men has been defeated.

At a meeting of the General Council, the question of Antarctic exploration was brought forward by the Royal Geographical Society, with a view to co-operation, and to the undertaking being unanimously advocated by the scientific societies of Great Britain and Ireland. The Council expressed their sympathy with, and approval of, the effort which was being made to organise an expedition for the exploration of the Antarctic Sea, but did not consider that any further action could usefully be taken by them at present.

As to the official affairs of the Association, Prof. Schäfer has been elected General Secretary in the place of Sir Douglas Galton, the present President. Sir W. H. Flower has been elected to represent the Association at the International Congress of Zoology at Leyden.

The retiring members of the Council were Prof. Lankester, Prof. Liveing, Mr. Preece, Prof. Reinold, and Prof. J. J. Thomson; and the new members elected to serve on the Council were Prof. Vernon Harcourt, Prof. Poulton, Prof. W. N. Shaw, Mr. Thiselton-Dyer, and Prof. J. M. Thomson.

The General Committee resolved on Monday that Sir Joseph Lister be appointed President-elect for the meeting at Liverpool next year. Prof. Herdman, Mr. J. C. Thompson, and Mr. W. E. Willink were appointed local secretaries for that meeting, and Mr. R. Bushell local treasurer. The Vice-Presidents-elect nominated for the meeting were the Lord Mayor of Liverpool (1896), the Earl of Sefton, the Lord-Lieutenant of the County of Lancaster, the Earl of Derby, Sir W. B. Forwood, Sir H. E. Roscoe, Mr. W. Rathbone, and Mr. W. Crookes. An invitation to hold the meeting in 1897 in Toronto, supported by cordial letters from British Columbia, from the University of Toronto, and Colleges of Manitoba, was accepted.

The following is a synopsis of the grants of money appropriated to scientific purposes by the General Committee this morning. The names of the members entitled to call on the General Treasurer for the respective grants are prefixed:—

	£	s.	d.
Mathematics and Physics.			
Prof. Carey Foster—Electrical Standards (and unexpended balance in hand)	£5	0	0

PRESIDENTS' ADDRESSES (*continued*).

SECTION C.

GEOLOGY.

Underground in Suffolk and its Borders.

Opening Address by W. Whitaker, B.A., F.R.S., F.G.S.

When the British Association revisits a town it is not unusual for the Sectional Presidents to refer to the addresses of their local predecessors, and to allude to the advance of their science since the former meeting. I have at all events tried to follow this course, with the sad result of having to chronicle a falling back rather than an advance in our methods of procedure; for at the meeting of 1851 all the Sectional Presidents had the wisdom not to give an address, and of all the inventions of later years I look upon the presidential address as perhaps the worst.

Had I the courage of my opinion I should not now trouble you; but an official life of over thirty-eight years has led me to do what I am told to do, and to suppress my own ideas of what is right. After all it is the fault of the Sections themselves that they should suffer the evil of addresses. They could disestablish the institution without difficulty.

On these occasions it is not usual to allude to the personal losses our science has had in the past year; but there are times when the lack of a familiar presence can hardly be passed over, and since we last met we have lost one of our most constant friends, who had served us long and well, and had been our Secretary for a far longer time than any other holder of that office. When we were at Oxford last summer none of us could have thought that it was our last meeting with William Topley.

I do not now mean to say anything on the origin or on the classification of the various divisions of the Crag and of the Drift that occur so plentifully around us, and form the staple interest of East Anglian geology. These subjects, which are the more interesting from being controversial, I leave to my brother-hammerers, and without claiming the credit of magnanimity in so doing, having said what I had to say on them in sundry Geological Survey Memoirs. The object of this address is to carry you below the surface, and to point out how much our knowledge of the geology of the county in which we meet has been advanced by workers in another field, by engineers and others in their search for water. As far as possible allusion will be made only to work in Suffolk; but we must occasionally invade the neighbouring counties.

This kind of evidence has chiefly accumulated since the meeting of the Association at Ipswich, in 1851; for of the 476 Suffolk wells of which an account, with some geologic information, has been published, only sixty-eight were noticed before that year, all but two of these being in a single paper. The notes on all these wells are now to be found in twelve Geological Survey Memoirs that refer to the county. Number alone, however, is not the only point, and many of the later records are marked by a precision and a detail rarely approached in the older ones. It should be stated that in the above and in the following numbers strict accuracy is not professed, nor is it material. A slight error in the number of the wells, one way or the other, would make practically no difference to the general conclusions.

Now let us see how these records affect our knowledge of the various geologic formations, beginning with the newest and working downward.

The Drift.

Under this head, as a matter of convenience for the present purpose, we will include everything above the Chillesford Clay. There is no need for refinement of classification, and the thin beds that come in between that Clay and the Drift in some parts do not affect the evidence we have to deal with.

As a matter of fact it is only from wells that we can tell the thickness of the Drift over most of the great plateau that this formation chiefly forms; open sections through a great thickness of Drift, to its base, are rare, except on the coast.

There is often some doubt in classifying the beds, the division between Drift and Crag being sometimes hard to make in sections of wells and borings; but from an examination of the records of these Suffolk sections that pass through any part of the Drift Series (as defined above) we find that no less than 173 show a thickness of 50 feet and upward, whilst of these 34 prove no less than 100 feet of Drift, many reaching to much more. Of the two that are said to show a thickness of over 200 feet and the one other said to be more than 300 feet deep in Drift, we

can hardly feel certain: but such amounts have been recorded with certainty as occurring in the neighbouring county of Essex.

These great thicknesses (chiefly consisting of Boulder Clay) show the importance of the Drift, and the impossibility of mapping the formations beneath with any approach to accuracy, on the supposition that the Drift is stripped off, as is the case in the ordinary geologic map. The records also show the varying thickness of the Drift, and how difficult it often is therefore to estimate the thickness at a given spot. Sometimes the sections seem to point to the existence of channels filled with Drift, such as are found also in Essex and in Norfolk; and it may be noted that in the northern inland part of the former county, one of these channels has been traced, though of course not continuously, for some eleven miles along the valley of the Cam, and at one place to the depth of 340 feet (or nearly 140 below sea-level), the bottom of the Drift moreover not having been reached even then. A channel of this sort seems to occur close to us, in the midst of the town of Ipswich, where, by St. Peter's, one boring has pierced 70 feet of Drift, and another 127, in ground but little above the sea-level.

As the Drift sands and gravels, that in many places occur below the Boulder Clay, often yield a fair amount of water, the proof of their occurrence and of the thickness of the overlying clay is of some practical good.

The Crag.

On this geologic division we have a less amount of information, as would be expected from the fact that it is not nearly so widespread as the Drift, and this information is confined to the Upper, or Red, Crag, the Lower, or Coralline, Crag occurring only over a very small area, and no evidence of its underground extension being given by wells.

What we learn of the Red Crag, however, is of interest, several wells having proved that it is far thicker underground than would have been supposed from what is seen where its base crops out. One characteristic, indeed, of this sandy deposit, in the many parts where it can be seen from top to bottom, is its thinness, as in such places it rarely reaches a thickness of 40 feet. But, on the other hand, wells at Hoxne seem to prove more than 60 feet of Crag, whilst at Saxmundham the formation is 100 feet thick, and at Leiston and Southwold over 140. Further north, just within the border of Suffolk, there is, at Beccles, a thickness of 80 feet of sand, or, with the overlying Chillesford Clay, a total of 95. Our underground information has, then, trebled the known thickness of the Upper Crag of Suffolk.

It has also shown that at some depth underground the colour-name is a misnomer, the shelly sands being light-coloured and not red. This is the case too with some other deposits, which owe their reddish-brown colour at the surface to peroxide of iron. Presumably the iron-salt is in a lower state of oxidation until it comes within reach of surface-actions. This seems to point to the risk of taking colour as the mark of a geologic formation.

Eocene Tertiaries.

Below the Crag there is a great gap in the geologic series, and we come to some of the lower of the Tertiary formations, about which little had been published, as regards Suffolk, before the work of the Geological Survey in the county. It seems as if the special interest in the more local Crag had led observers to neglect these beds, which had been amply noticed in other parts.

We have records of more than forty wells in Suffolk that are partly in these deposits, and of these thirty-six reach down to the Chalk, twenty giving good sections from the London Clay to the Chalk. The thickness of the Lower London Tertiaries (between those formations) thus proved varies from 30 to 79½ feet, the higher figure being much greater than anything shown at the outcrop. The greatest recorded thickness is at Leiston, where, moreover, the top 26 feet of the 79½ may belong to the uppermost and most local of the three divisions of the series, the Oldhaven Beds, of very rare occurrence in the county. The next greatest thickness is at Southwold, where the whole has been classed as Reading Beds (the persistent division), though here and elsewhere it is possible that the underlying Thanet Beds are thinly represented. It is noteworthy that at both these places, where the Lower London Tertiaries are thick, they are also at a great depth, beginning at 252½ and 218 feet respectively, which looks as if, like the Crag, they thickened in their underground course away from the outcrop.

The important evidence given by these wells, however, is not as regards thickness; it is to show the underground extent of the older Tertiary beds, beneath the great sheet of Crag and Drift that prevents them from coming to the surface north-eastward from the neighbourhood of Woodbridge. It is clear that over this large tract we can know nothing of the beds beneath the Crag otherwise than from wells and borings: and, until these were made, our older geologic maps cut off the older Tertiary beds far south of the parts to which we now know that they reach, though hidden from our sight. No one, for instance, would have imagined many years ago that at Southwold the Chalk would not be touched till a boring had reached the depth of 323 feet, or some 280 below sea-level, nor that at Leiston those figures would have been about 297 and 240.

It is from calculations based on the levels of the junction of the Chalk and the Tertiary beds in many wells that the line engraved on the Geological Survey map as the probable boundary of the latter beds under the Crag and Drift has been drawn. From what has gone before, however, as to the great irregularity in the thickness of the Drift, it is clear that this line must be taken only as approximate, and open to correction as further evidence is got; albeit the junction of the Chalk and the Tertiary beds is found to be here, as elsewhere, fairly even, along an inclined plane that sinks towards the coast.

Cretaceous Beds.

Though the *Chalk* is reached by very many wells, yet we get less information about it, by reason of its great thickness. Moreover, the great amount of overlying beds in many cases is a bar to deep exploration.

Of our Suffolk wells there are forty which go through 100 feet or more of Chalk. Of these twenty go through 200 feet or more, half of these to 300 or more, and again half of the ten to 400 or more, a very exact piece of geometric progression, or more strictly, retrogression. Although two wells pass through the great thickness of more than 800 feet of Chalk, yet neither of them gives us the full thickness of the formation; for the 816 feet at Landguard Fort do not reach to the base, whilst the 843 (or 817) feet at Combs, near Stowmarket, do not begin at the top.

As in no case yet recorded has the Chalk been pierced from top to bottom in Suffolk (a defect that will be supplied during this meeting by the description of the Stutton boring), that is to say, no boring has gone from the overlying older Tertiary beds to the underlying Gault, we must now, therefore, cross the border of the county to get full information as to the thickness of the Chalk; and we have not far to go, for the well-known Harwich boring passes through the whole of the Chalk, proving a thickness of 890 feet. It is almost certain, indeed, that this should be given as a few feet more, for the 22 feet next beneath, which have been described as Gault mixed with Greensand, is probably in part the green clayey glauconitic base of the Chalk Marl. We may fairly add to this number 5 feet (as also in the case of the Combs boring), and may say that, in round numbers, the Chalk reaches a thickness of about 900 feet in the south-eastern part of Suffolk. Toward the northern border of the county it is probably more, as the deep boring at Norwich passes through nearly 1160 feet of Chalk, and that without beginning at the top of the formation.

Of our recorded Suffolk wells only three reach the base of the Chalk, at Mildenhall, Culford and Combs; consequently we have little knowledge of the divisions of the Chalk. These divisions, indeed, are of comparatively late invention, having been evolved since the publication of many of the deep sections that have been referred to.

If the Upper Chalk at Harwich goes as far down as the flints, then we must allow it to be 690 feet thick, leaving little more than 200 for the Middle and Lower Chalk together. At Landguard Fort, from the same point of view, the Upper Chalk would certainly be 500 feet thick, and one cannot say how much more.

At Combs, on the other hand, flints have been recorded as present only in the top 27 feet of the Chalk; but whilst this may have been owing in part to the boring having passed between fairly scattered nodules, and in part, perhaps, to insufficient care in observation, at Harwich it is possible that some flints may have been carried down in the process of boring.

What evidence we have tends to show, however, that the Upper Chalk forms a good deal more than half, and perhaps about two thirds, of the formation, the Middle and Lower Chalk

being rather thin. This agrees with what is found in other parts where the Chalk is thick, extra thickness being chiefly due to the highest division. The glauconitic marly bed at the base seems to be well developed and to be underlain by the Gault clay; so that we have no good evidence of the occurrence of Upper Greensand. This division may be thinly represented at Mildenhall, but it is difficult to classify some of the beds passed through in the old boring there.

As far as the *Gault* is concerned, little, of course, is known; yet that little points to this formation being unusually thin, presumably only 73 feet from top to bottom at Culford, and probably not more than between 50 and 60 at and near Harwich. In the north-western part of the neighbouring county of Norfolk it is well known to be still less, the clay thinning out northward along the outcrop, until at last there is nothing but a few feet of Red Chalk between the carstone of the Lower Greensand and the Chalk. The Gault being of much greater thickness around and under other parts of the London Basin, this thinning in Norfolk and Suffolk is noteworthy. The absence of the more inconstant Upper Greensand is to be expected in most places, and calls for no remark: it may, however, be noted that geologists are coming to the conclusion that these two divisions are really parts of one formation, and one result of this geologic wedding is for the inconstancy of one partner to be greatly compensated by the constancy of the other.

The *Lower Greensand* has been found in one deep boring only, at Culford, in the western part of the county, where it is represented by $32\frac{1}{2}$ feet of somewhat exceptional beds. This slight thickness prepares us for underground thinning, and in the far east of the county the formation is presumably absent, there being no trace of it at Harwich or at Stutton.

With the Cretaceous beds we pass from the regular orderly succession of geological formations; indeed, it may be said that when we reach the base of the Gault we pass out of the region of facts into the realm of speculation.

We have come, then, to perhaps the most interesting problem in the geology of the Eastern Counties, to the consideration of the question, What rocks underlie the Cretaceous beds at great depths? In dealing with this I must ask your patience for frequent excursions outside our special district, and sometimes to lead far away from it.

Beyond the outcrop of the lower beds of the Cretaceous Series in Cambridgeshire and Norfolk, we find of course a powerful development of the great Jurassic Series; but the only two recorded deep borings in and near Suffolk that have pierced through the Cretaceous base, at Culford on the north-west and at Harwich on the south-east, show not a trace of anything Jurassic: they pass suddenly from Cretaceous into far older rocks. And here a paper that is to be brought before you must be anticipated, to a slight extent, by adding that the trial-boring at Stutton shows just the same thing, the Gault resting directly on a much older rock, which cannot be classed as of Secondary age.

There is no need now to discuss the literature of the old rocks underground in south-eastern England, that has often been done. We may take the knowledge of what has been shown by the various deep borings as common property, and may use it freely, without troubling to state the source of each piece of information, and I will not therefore burden this address with references. I had indeed thought of supplementing a former account by noticing the later literature of the subject; but decided to spare you from the infliction, and myself from the trouble of inflicting: though it may be convenient to add, in the form of an Appendix, a list of the chief papers on the subject that have been published since the question was discussed at length in 1889, in an official memoir on the geology of London, and to supply some omissions in that work. Nor do I propose to enter into any special criticism of papers on the subject that have appeared of late years; this is hardly the occasion for controversy, which may well be put off to a more convenient season. Some general remarks, however, I shall have to make after putting the facts before you.

There are ten deep borings reaching to old rocks in the London Basin, of which accounts have been published. We know that in four of these (Meux's, Streatham, Richmond and Dover) Jurassic beds separate those rocks from the Cretaceous beds, whilst there are six in which these last rest direct on old rocks (Ware, Cheshunt, Kentish Town, Crossness, Culford, and Harwich). Stutton of course makes a seventh. The Jurassic r[illegible] any in the northern borings, either in London or still further southward, and in one case only (Dover) is there any considerable thickness of these: in the other three they are from $38\frac{1}{2}$ to $87\frac{1}{2}$ feet thick. As far as regards Suffolk and its borders we may therefore disregard them, except in the far west, near their outcrop, and we may pass on to consider the older rocks that have been found.

So far the occurrence, next beneath the Cretaceous or Jurassic beds, of Silurian, Devonian, and Carboniferous rocks has been proved, whilst in some cases we are still doubtful as to the age of the old rocks found. In five cases distinctive fossils have been found (Ware, Cheshunt, Meux's, Dover, and Harwich), but in five others they have not (Kentish Town, Crossness, Richmond, Streatham, and Culford), and it is in the latter group too that the character of the beds leaves their age in doubt. So far another must be added to these, as no fossil has yet been found in the old rocks at Stutton.

Of the above ten deep borings in the London Basin (using that term in the widest sense, as including the Chalk tract that everywhere surrounds the Tertiary beds) we owe nine to endeavours to get water from deep-seated rocks, and in addition to these nine we have several other deep borings, which though not carried through to the base of the Secondary rocks, yet give us much information concerning those beds (at Holkham, Norwich, Combs, Winkfield, London, Loughton, Chatham, and Dover). In one case only, that of Dover, has the work been done for the purpose of exploration, but now, after a few years' interval, a second trial has been made at Stutton.

Now both of these borings were started for a much more definite object than merely to prove the depth to older rocks, or the thickness of the Cretaceous and Jurassic Series. There is one particular division of those older rocks that has a distinct fascination for others than geologists. We, happily, are content to find anything and to increase our knowledge in any direction, but naturally those who are not geologists, as well as many who are, like to find something of immediate practical value. As already shown, we owe much knowledge of the underground extension of formations to explorations for water; it has now become the turn of geologists to help those who would like to find that much less general, though nearly as needful and certainly more valuable thing, *coal*.

The first place to suggest itself to those geologists who had worked at this question, as a good site for trial, was the neighbourhood of Dover, and for various good reasons. The trial has been made, and successfully, several hundred feet of Coal Measures having been found, without reaching their base, but with several beds of workable coal.

Beyond that neighbourhood, however, geologists are not in such accord, and generally speaking, fairly good reasons can be given both for and against the selection of many tracts for trial, except in and near London, where no geologists would recommend it, from the evidence in our hands.

Let us then shortly review the evidence that we have on the underground extension of the older rocks in south-eastern England, with a view of considering the question of the possibility of finding Coal Measures in any of the folds into which those rocks have probably, nay almost certainly, been thrown.

The area within which the borings that reach older rocks in the London Basin is enclosed is an irregular pentagon, from near Dover, on the south-east, to Richmond on the west, thence to Ware, thence to Culford on the north, thence to Harwich, and thence southward to Dover, the greatest distance between any borings being from Dover to Culford, about eighty-six miles. It is therefore over a large tract, extending of course beyond the boundaries sketched above, that we have good reason to infer that older rocks are within reasonable distance of the surface, nowhere probably as much as 1000 feet, and mostly a good deal less.

We must now consider some evidence outside the tract hitherto dealt with. Southward of the central and eastern parts of the London Basin we have evidence that the Lower Cretaceous beds thicken greatly, from what is seen over their broad outcrop between the North and South Downs. We know also, from the Dover and Chatham borings, that the Upper and Middle Jurassic beds come in to the south-east, whilst the Sub-Wealden Exploration, near Battle, proves that those divisions thicken greatly southward, the latter not having been bottomed at the depth of over 1900 feet, at that trial-boring.

Westward, however, near Burford in Oxfordshire, and some miles northward of the nearest part of the London Basin, Carboniferous rocks have been found at the depth of about 1180

feet, these being separated from the thick Jurassic beds (including therein the Liassic and Rhætic) by perhaps 420 of Trias. They consist of Coal Measures, which were pierced to the depth of about 230 feet.

In and near Northampton, north-eastward of the last site, and still further from the northern edge of the London Basin, the like occurs; but the beds found are older than the Coal Measures, and the Trias is thin, not reaching indeed to 90 feet in thickness, and being absent in one case. At one place, too, the Carboniferous beds have been pierced through, with a thickness of only 222 feet, when Old Red Sandstone was found, and in another place still older rock seems to have been found next beneath the Trias. The depth to the rocks older than the Trias, where they were reached, was 677, 738, and 790 feet, or respectively 395, 460, and 316 below sea-level. Some of these figures must be taken as somewhat approximate, though they are near enough to the truth for practical purposes.

A boring at Bletchley, to the south, reached granitic rocks at the depths of 378½ and 401 feet: but these rocks seem to be only boulders in a Jurassic clay: their occurrence, however, is suggestive of the presence of older rocks at the surface no great way off, in Middle Jurassic times.

Much further northward, at Scarle, south-west of Lincoln, the older rocks have been reached at the depth of about 1500 feet, all but 141 of which are Trias, and they begin with the Permian (which crops out some eighteen miles westward), the Carboniferous occurring after another 400 feet, and having been pierced to 130.

We have then evidence that over a large part of south-eastern England, reaching northward and westward of the London Basin, though the older rocks are hidden by a thick mantle of Jurassic, Cretaceous, and Tertiary beds, yet they seem to be rarely at a depth that would be called very great by the coal-miner. They are distinctly within workable depths wherever they have been reached.

There is no area of old rocks at the surface in our island, south of the Forth, in which Coal Measures are not a constituent formation. Truly, further north, in the great tract of Central and Northern Scotland there are no Carboniferous rocks; but we can hardly say that none ever occurred, at all events in the more southern parts. We know, though, that on the west and north Jurassic and Triassic beds rest on formations older than the Carboniferous.

It is not, however, to this more northern and distant tract that we should look for analogy to our underground plain of old rocks; rather should we look to more southern parts, to Wales and to central and northern England, where Coal Measures are of frequent occurrence. On the principle of reasoning from the known to the unknown, I cannot see why we should expect anything but a like occurrence of Coal Measures, in detached basins, in our vast underground tract of old rocks.

What, then, is the evident conclusion from what we know and from what we may reasonably infer? Surely that trials should be made to see if such hidden coal-basins can be found.

One trial has been made, and it has succeeded; the Dover boring has proved the presence of coal underground in Eastern Kent, along the line between the coal-fields of South Wales and of Bristol on the west, and those of Northern France and of Belgium on the east.

The long gap between the distant outcrops of the Coal Measures near Bristol and Calais has been lessened very slightly by the working of coal under the Triassic and Jurassic beds near the former place, but much more by our brethren across the narrow sea, the extent of the Coal Measures, beneath the Jurassic and Cretaceous beds, having not only been proved by the French and the Belgians along their borders, but the coal having been largely worked. At last, we too have still further decreased the gap, by the Dover boring, a work that I trust is to be followed by other work along the same line.

But is this the only line along which we are to search? Are we to conclude that the only coal-fields under our great tract of Cretaceous beds (where these are either at the surface or covered by Tertiary beds) are in Kent, Surrey, and other counties to the west? Have we no coal-fields but those of Bristol and of South Wales? The bounds of our midland and northern coal-fields have been extended by exploration beneath the New Red Series; are we to stop here and to assume that there can be no further underground extension of the Coal Measures south-eastward? This seems hardly a wise course, and is certainly a very unenterprising one. It seems to me rather that the right thing to be done is to try to find out the real state of things, by means of borings.

There are, of course, objectors in this as in other matters. Some may say that it is silly to try in Suffolk, and that Essex gives a better chance of success. Others, again, may prefer Norfolk. And yet others may argue that there is no chance of finding Coal Measures in any of those three counties. But I must confess my inability to understand this line of reasoning; the fact is that the data we have are few and far between, and that we want more. It is really of little use to bandy words, and I do not now mean to take up the matter in detail. We cannot get at the truth except by actual work; justification by faith will not hold in this case, still less justification by unfaith.

Let us hark back a little and call to mind what has happened in the past. I remember the time when certain geologists disbelieved in the possibility of the occurrence of Coal Measures anywhere in south-eastern England, it being argued that the formation thinned out before it could get so far eastward. Then this view was somewhat varied, and it was inferred, from certain observed facts, that even if Coal Measures did reach underground into these benighted parts, they would be without workable coal, and so practically useless.

Now for some years nothing occurred to upset the prophets of evil, that is to say, no fact came to light. There were not wanting inferences to the contrary, but it remained practically a matter of opinion. One day, however, the needful fact came, and the first boring made specially to test the question (at Dover) disproved both the above negative theories by finding Coal Measures with workable coal. Let us hope that a like result may happen in East Anglia, and that the pessimists may again be in the wrong.

We should not, however, fall into the opposite error, that of optimism. We must not expect an immediate success like that at Dover. We are here much further from any known coal-field. Advertisements of various wares sometimes tell us that "one trial will suffice," but it is not so in this case. We should not be content until many borings have been made, and we should not be despondent if, after sites have been selected to the best of our judgment, we begin with a set of borings that are unsuccessful in finding coal.

At the time of writing I cannot say that the Stutton boring is a success or a failure as far as coal is concerned, but I am quite ready to accept the latter without being discouraged. Whatever it is you may know during our meeting; it is certainly a success in the matter of reaching the old rocks at a depth of less than 1000 feet. We should remember that every boring is almost certain to give us some knowledge that may help in future work.

There is a further point, however, to be taken into account. A boring that may at first seem to be a failure, from striking beds older than the Coal Measures, may some day turn out otherwise. The coal-field along the borders of France and Belgium is sometimes affected by powerful and peculiar disturbances, by faults of comparatively gentle inclination (far removed from the usual more or less vertical displacements) which have thrown Coal Measures beneath older beds in large tracts. This is no mere theory, though advanced as such at first by some continental geologists, who have had the great satisfaction of seeing their theory adopted by practical men, and proved to be true, much coal being worked below the older beds that have been pushed above the Coal Measures by the over-thrust faults.

Our trial-work, of course, does not yet lead us to consider such disturbances as those alluded to. We have at first to assume a normal succession of formations, and not to carry on explorations in beds that can be proved to be older than the Coal Measures; but the time may come when it will be otherwise.

Another matter to which attention has been drawn by our foreign friends is an apparent general persistence of disturbances along certain lines, or in other words, the recurrence of disturbances in newer beds in those parts where earlier movements had affected older beds; so that, reasoning backward, where we see marked signs of disturbance for long distances in beds at or near the surface, there we may expect to find pre-existing disturbances of the older beds beneath. This, however, is a somewhat controversial question, and much remains to be done on it; but should it be proved as a general rule it may have much effect on our underground coal.

Finally, the question of the possibility of finding and of work-

[illegible] parts of south-eastern England is not merely of [illegible]; it is of national importance. The time must come when the coal-fields that we have worked for years will be more or less exhausted, and we ought certainly to look out ahead for others, so as to be ready for the lessening yield of those that have served us so well. It is on our coal that our national prosperity largely, one may say chiefly, depends, and, as far as we can see, will depend. Let us not neglect any of the bounteous gifts of nature, but let us show rather that we are ready to search for the treasures that may be hidden under our feet, and the finding of which will result in the continued welfare of our native land.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY WILLIAM A. HERDMAN, D.Sc., F.R.S., F.L.S., F.R.S.E., PROFESSOR OF NATURAL HISTORY IN UNIVERSITY COLLEGE.

THIS year, for the first time in the history of the British Association, Section D meets without including in the range of its subject-matter the Science of Botany. Zoology now remains as the sole occupant of Section D that "Fourth Committee of Sciences," as it was at first called, more than sixty years ago, when our subject was one of that group of biological sciences, the others being Botany, Physiology, and Anatomy. These allied sciences have successively left us. Like a prolific mother our Section has given rise one after another to the now independent Sections of Anthropology, Physiology, and Botany. Our subject-matter has been greatly restricted in scope, but it is still very wide—this year, when Section I, devoted to the more special physiology of the medical physiologist, does not meet, perhaps a little wider than it may be in other years, since we are on this occasion credited with the subject "Animal Physiology"—surely *always* an integral part of Zoology! It is to be hoped that this Section will always retain that general and comparative physiology which is inseparable from the study of animal form and structure. The late Wayntlete Professor of Physiology at Oxford, in his Newcastle address to this Section, said "that every appreciable difference in structure corresponds to a difference of function" (Burdon-Sanderson, "British Association Report" for 1889), and his successor, the present Waynflete Professor, has shown us "how pointless is structure apart from function, and how baseless and unstable is function apart from structure" (Gotch, "Presidential Address to Liverpool Biological Society," vol. ix., 1894) the "argument for the simultaneous examination of both" in that science of Zoology which we profess is, to my mind, irresistible.

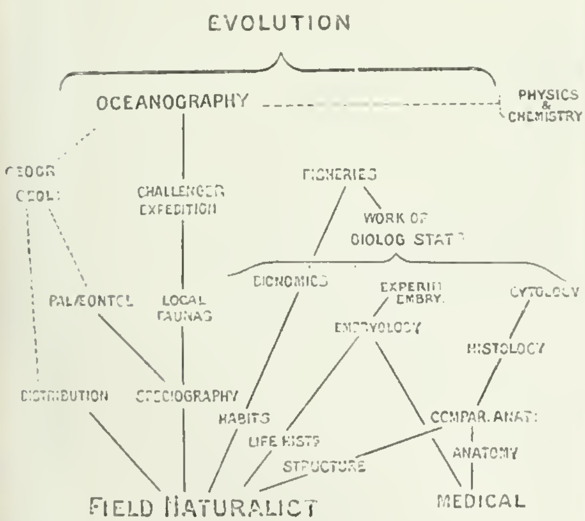
We include also in our subject-matter, besides the adult structure and the embryonic development of animals, their distribution both in space and time, the history and structure of extinct forms, speciography and classification, the study of the habits of animals and all that mass of lore and philosophy which has gathered around inquiries into instinct, breeding, and heredity. I trust that the discussion of matters connected with Evolution will always, to a large extent, remain with this Section D, which has witnessed in the past the addresses, papers, discussions, and triumphs of Darwin, Huxley, and Wallace.

When the British Association last met in Ipswich, in 1851, Section D, under the presidency of Prof. Henslow, still included Zoology, Botany, and Physiology, and a glance through the volumes of reports for that and neighbouring years recalls to us that our subject has undergone great and striking developments in the forty-four years that have elapsed. Zoology was still *pre-Darwinian* though Charles Darwin was then in the thick of his epoch-making work—both what he calls his "plain barnacle work" and his "theoretic species work" (see "Life and Letters," vol. i. p. 380). Although the cell-theory had been launched a decade before, zoologists were not yet greatly concerned with those minute structural details which have since built up the science of Histology. The heroes of our science were then chiefly those glorious field naturalists, observers, and systematists who founded and established on a firm basis British Marine Zoology. Edward Forbes, Joshua Alder, Albany Hancock, were then in active work. George Johnston was at his zoophytes, Bowerbank at sponges, Busk at polyzoa. Forbes' short brilliant career was nearly run. He probably did more than any of his contemporaries to advance marine zoology. In the previous year, at the Edinburgh meeting of the Association, he and his friend MacAndrew had read their classic reports ("British Association Report" for 1850, p. 192 *et seq.*), "On the Investigation of British Marine Zoology by Means of the Dredge," and "On South European Marine Invertebrata," which mark the high-water level reached at that date, and for some time afterwards, in the exploration of our coasts and the explanation of the distribution of our marine animals. At the Belfast meeting, which followed Ipswich, Forbes exhibited his great map of the distribution of marine life in "Homoiozoic Belts." In November 1854 he was dead, six months after his appointment to the goal of his ambition, the professorship at Edinburgh, where, had he lived, there can be no doubt he would,

with his brilliant ability and unique personality, have founded a great school of Marine Zoology.

To return to the early fifties, Huxley—whose recent loss to science, to philosophy, to culture, we, in common with the civilised world, now deplore—at that time just returned from the memorable voyage of the *Rattlesnake*, was opening out his newly acquired treasures of comparative anatomy with papers on Siphonophora and on Sagitta, and one on the structure of Ascidians, in which he urged—fourteen years before Kowalevsky established it on embryological evidence in 1866—that their relations were with Amphioxus, as we now believe, rather than with the Polyzoa or the Lamellibranchiata, as had formerly been supposed. Bates was then on the Amazons, Wallace was just going out to the Malay Archipelago, Wyville Thomson, Hincks, and Carpenter, the successors of Forbes, Johnston, and Alder, were beginning their life-work. Abroad that great teacher and investigator, Johannes Müller, was training amongst his pupils the most eminent zoologists, anatomists, and physiologists of the succeeding quarter century. In this country, as we have seen, Huxley was just beginning to publish that splendid series of researches into the structure of nearly all groups in the animal kingdom, to which comparative anatomy owes so much.

In fact, the few years before and after the last Ipswich meeting witnessed the activity of some of the greatest of our British zoologists—the time was pregnant with work which has since advanced, and in some respects revolutionised our subject. It was then still usual for the naturalist to have a competent knowledge of the whole range of the natural sciences. Edward Forbes, for example, was a botanist and a geologist, as well as a zoologist. He occupied the chair of Botany at King's College, London, and the presidential chair of the Geological Section of the British Association at Liverpool in 1854. That excessive specialisation, from which most of us suffer in the present day, had not yet arisen; and in the comprehensive, but perhaps not very detailed, survey of his subject taken by one of the field naturalists of that time, we find the beginnings of different lines of work, which have since developed into some half-dozen distinct departments of zoology, are now often studied independently, and are in some real danger of losing touch with one another (see diagram).



The spendid anatomical and "morphological" researches of Huxley and Johannes Müller have been continued by the more minute histological or cellular work rendered possible by improvements of the microtome and the microscope, until at last in these latter years we investigate not merely the cellular anatomy of the body, but *the anatomy of the cell*—if indeed we are permitted to talk of "cell" at all, and are not rather constrained to express our results in terms of "cytomicrosomes," "somacules," or "idiosomes," and to regard our morphological unit, the cell, as a symbiotic community containing two colonies of totally dissimilar organisms (see Watasé in "Wood's Holl Biological Lectures," 1893). To such cytological investigations may well be applied Lord Macaulay's aphorism, "A point which yesterday was invisible is its goal to-day, and will be its starting-point to-morrow."

Somewhat similar advances in methods have led us from the life-histories studied of old to the new and fascinating science of embryology. The elder Milne-Edwards and Van Beneden knew that in their life-histories Ascidians produced tadpole-like young. Kowalevsky (1866) showed that in their embryonic stages these Ascidian tadpoles have the beginnings of their chief systems of organs formed in essentially the same manner and from the same embryonic layers as in the case of the frog's tadpole or any other typical young vertebrate; and now we are not content with less than tracing what is called the "cell-lineage" of such Ascidian embryos, so as to show the ancestry and descendants, the traditions, peculiarities of, and influences at work upon each of the embryonic cells—or areas of protoplasm—throughout many complicated stages. And there is now opening up from this a great new field of experimental and "mechanical" embryology, in which we seek the clue to the explanation of particular processes and changes by determining under what conditions they take place, and how they are affected by altered conditions. We are brought face to face with such curious problems as, Why does a frog's egg, in the two-celled stage, of which one-half has been destroyed, develop into half an embryo when it is kept with one (the black) surface uppermost, and into—not half an embryo, but—a whole embryo of *half the usual size* if kept with the other (the white) surface upwards. Apparently, according to the conditions of the experiment, we may get half embryos or whole embryos of half size from one of the first two cells of the frog's egg.[1]

One of the most characteristic studies of the older field naturalists, the observation of habits, has now become, under the influence of Darwinism, the "Bionomics" of the present day, the study of the relations between habit and structure and environment—a most fascinating and promising field of investigation, which may be confidently expected to tell us much in the future in regard to the competition between species, and the useful or indifferent nature of specific characters.

Other distinct lines of zoological investigation, upon which I shall not dwell, are geographical distribution and palæontology—subjects in which the zoologist comes into contact with, and may be of some service to his fellow-workers in geology. And there still remains the central avenue of the wide zoological domain—that of speciography and systematic zoology—which has been cultivated by the great classifiers and monographers from Linnæus to Hæckel, and has culminated in our times in the magnificent series of fifty quarto volumes, setting forth the scientific results of the *Challenger* Expedition; a voyage of discovery comparable only in its important and wide-reaching results with the voyages of Columbus, Gama and Magellan at the end of the fifteenth century. It is now so long since the *Challenger* investigations commenced that few I suppose outside the range of professional zoologists are aware that although the expedition took place in 1872 to 1876, the work resulting therefrom has been going on actively until now—for nearly a quarter of a century in all—and in a sense, and a very real one, will never cease, for the *Challenger* has left an indelible mark upon science, and will remain through the ages exercising its powerful, guiding influence, like the work of Aristotle, Newton, and Darwin.

Most of the authors of the special memoirs on the sea and its various kinds of inhabitants, have interpreted in a liberal spirit the instructions they received to examine and describe the collections entrusted to them, and have given us very valuable summaries of the condition of our knowledge of the animals in question, while some of the reports are little less than complete monographs of the groups. I desire to pay a tribute of respect to my former teacher and scientific chief, Sir Wyville Thomson, to whose initiative, along with Dr. W. B. Carpenter, we owe the first inception of our now celebrated deep-sea dredging expeditions, and to whose scientific enthusiasm, combined with administrative skill, is due in great part the successful accomplishment of the *Lightning*, the *Porcupine*, and the *Challenger* Expeditions. Wyville Thomson lived long enough to superintend the first examination of the collections brought home, their division into groups, and the allotment of these to specialists for description. He enlisted the services of his many scientific friends at home and abroad, he arranged the general plan of the work, decided upon the form of publication, and died in

[1] See Morgan, "Anat. Anzeig.," 1895, x. Bd. p. [illegible], and recent papers by Roux Hertwig, Born, and O. Schultze.

1882. After seeing the first ten or twelve zoological reports through the press.

Within the last few months have been issued the two concluding volumes of this noble series, dealing with a summary of the results, conceived and written in a masterly manner by the eminent editor of the reports, Dr. John Murray. An event of such first-rate importance in zoology as the completion of this great work ought not to pass unnoticed at this zoological gathering. I desire to express my appreciation and admiration of Dr. Murray's work, and I do not doubt that the Section will permit me to convey to Dr. Murray the congratulations of the zoologists present, and their thanks for his splendid services to science. Murray, in these "Summary" volumes, has given definiteness of scope and purpose, and a tremendous impulse, to that branch of science—mainly zoological—which is coming to be called

OCEANOGRAPHY.

Oceanography is the meeting ground of most of the sciences. It deals with botany and zoology, "including animal physiology"; chemistry, physics, mechanics, meteorology, and geology all contribute, and the subject is of course intimately connected with geography, and has an incalculable influence upon mankind, his distribution, characteristics, commerce, and economics. Thus oceanography, one of the latest developments of marine zoology, extends into the domain of, and ought to find a place in, every one of the Sections of the British Association.

Along with the intense specialisation of certain lines of zoology in the last quarter of the nineteenth century, it is important to notice that there are also lines of investigation which require an extended knowledge of, or at least make use of the results obtained from, various distinct subjects. One of these is oceanography, another is bionomics, which I have referred to above, a third is the philosophy of zoology, or all those studies which bear upon the theory of evolution, and a fourth is the investigation of practical fishery problems—which is chiefly an application of marine zoology. Of these four subjects—which while analytic enough in the detailed investigation of any particular problem, are synthetic in drawing together and making use of the various divergent branches of zoology and the neighbouring sciences—oceanography, bionomics, and the fisheries' investigation, are most closely related, and I desire to devote the remainder of this address to the consideration of some points in connection with their present position

Dr. Murray, in a few only too brief paragraphs at the end of his detailed summary of the results of the *Challenger* Expedition, which I have alluded to above, states some of the views, highly suggestive and original, at which he has himself arrived from his unique experience. Some of his conclusions are very valuable contributions to knowledge, which will no doubt be adopted by marine zoologists. Others, I venture to think, are less sound and well founded, and will scarcely stand the test of time and further experience. But for all such statements, or even suggestions, we should be thankful. They do much to stimulate further research, they serve, if they can neither be refuted nor established, as working hypotheses; and even if they have to be eventually abandoned, we should bear in mind what Darwin has said as to the difference in their influence on science between erroneous facts and erroneous theories. "False facts are highly injurious to the progress of science, for they often endure long; but false views, if supported by some evidence, do little harm, for every one takes a salutary pleasure in proving their falseness; and when this is done, one path towards error is closed, and the road to truth is often at the same time opened" (Darwin, "The Descent of Man," second edit. 1882, p. 606).

With all respect for Murray's work, and fully conscious of my own temerity in venturing to differ from one who has had such unrivalled experience of the sea and its problems, I am constrained to express my disagreement with some of his conclusions. And I am encouraged to do so by the belief that Murray will recognise that the best compliment which zoologists can pay to his work is to give it careful, detailed consideration, and discuss it critically. He will, I am sure, join me in the hope that, [illegible] or [illegible] prove the false ones, we may be able, by their elimination, to close a "path towards error," and possibly open the road to truth."

One of the points upon which Murray lays considerable stress, and to the consideration of which he devotes a prominent position in his "General Observations on the Distribution of Marine Organisms," is the presence of what he has called a "mud-line" around coasts at a depth of about one hundred fathoms. It is the point "at which minute particles of organic and detrital matters in the form of mud begin to settle on the bottom of the ocean." He regards it as the great feeding ground, and a place where the fauna is most abundant, and from which there have hived off, so to speak, the successive swarms or migrations which have peopled other regions—the deep waters, the open sea, the shallow waters and the estuaries, fresh waters, and land. Murray thus gives to his mud-line both a present and an historic importance which can scarcely be surpassed in the economy of life on this globe. I take it that the historic and the present importance stand or fall together—that the evidence as to the origin of faunas in the past is derived from their distribution at the present day, and I am inclined to think that Murray's opinion as to the distribution of animals in regard to the mud-line is not entirely in accord with the experience of specialists, and is not based upon reliable statistics. Murray's own statement is ("*Challenger* Expedition, Summary," vol. ii. p. 1433):—"A depth is reached along the continental shores facing the great oceans immediately below which the conditions become nearly uniform in all parts of the world, and where the fauna likewise presents a great uniformity. This depth is usually not far above nor far below the 100-fathom line, and is marked out by what I have elsewhere designated as the *Mud-line*. . . . Here is situated the great feeding ground in the ocean . . ." and he then goes on (p. 1434) to enumerate the Crustaceans, such as species of *Calanus*, *Euchæta*, *Pasiphæa*, *Crangon*, *Calocaris*, *Pandalus*, *Hippolyte*, many amphipods, isopods, and immense numbers of schizopods, which swarm, with fishes and cephalopods, immediately over this mud deposit. Now I venture to think that the experience of some of those who have studied the marine zoology of our own coasts does not bear out this statement. In the first place, our experience in the Irish Sea is that mud may be found at almost any depth, but is very varied in its nature and in its source. There may even be mud laid down between tide marks in an estuary where a very considerable current runs. A deposit of mud may be due to the presence of an eddy or a sheltered corner in which the finer particles suspended in the water are able to sink, or it may be due to the wearing away of a limestone beach, or to quantities of alluvium brought down by a stream from the land, or to the presence of a submerged bed of boulder clay, or even, in some places, to the sewage and refuse from coast towns. Finally, there is the deep-water mud, a very stiff blue-grey substance which sets, when dried, into a firm clay, and this is, I take it, the mud of which Dr. Murray writes. But in none of these cases, and certainly not in the last mentioned, is there in my experience or in that of several other naturalists I have consulted, any rich fauna associated with the mud. In fact, I would regard mud as supporting a comparatively poor fauna as compared with other shallow water deposits.

For practical purposes, round our own British coasts, it is still convenient to make use of the zones of depth marked out by Forbes. The first of these is the "Littoral zone," the space between tide marks, characterised by the abundance of sea-weeds, belonging to the genera *Lichina*, *Fucus*, *Enteromorpha*, *Polysiphonia*, and others, and by large numbers of individuals belonging to common species of *Balanus*, *Mytilus*, *Littorina*, *Purpura*, and *Patella* amongst animals. The second zone is the "Laminarian," which extends from low-water mark to a depth of a few fathoms, characterised by the abundant growth of large sea-weeds belonging to the genera *Laminaria*, *Alaria*, and *Himanthalia*, and by the presence of the beautiful red sea-weeds (Florideæ). There is abundance of vegetable food, and animals of all groups swarm in this zone, the numbers both of species and of individuals being very great. The genera *Helcion*, *Trochus*, and *Lacuna* are characteristic molluscan forms in our seas. Next comes Forbes' "Coralline" zone, badly so named, extending from about ten to forty or fifty fathoms or so. Here we are beyond the range of the ordinary sea-weeds, but the calcareous, coral-like Nullipores are present in places in such abundance as to make up deposits covering the floor of the sea for miles. Hydroid zoophytes and polyzoa are also abundant, and it is in this zone that we find the shell-beds lying off our coasts, produced by great accumulations of species of *Pecten*, *Ostrea*, *Pectunculus*, *Fusus*, and *Buccinum*, and forming rich feeding grounds for many of our larger fishes. All groups of marine animals are well represented in this zone, and *Antedon*, *Ophiothrix*, *Ophioglypha*, *Ebalia*, *Inachus*, and *Eurynome*, may be mentioned as characteristic genera. Lastly, there is what may be appropriately called the zone of deep mud (although Forbes

did not call it so), extending from some fifty fathoms down to (in our seas) one hundred or so. The upper limit of this zone is Murray's mud-line. We come upon it in the deep fjord-like sea-lochs on the west of Scotland, and in the Irish Sea to the west of the Isle of Man.

Now of these four zones, my experience is that the last—that of the deep mud—has by far the poorest fauna both in species and in individuals. The mud has a *peculiar* fauna and one of great interest to the zoologist, but it is not a *rich* fauna. It contains some rare and remarkable animals not found elsewhere, such as *Calocaris macandreae*, *Panthalis oerstedi*, *Lipobranchius jeffreysi*, *Brissopsis lyrifera*, *Amphiura chiajii*, *Isocardia cor*, and *Sagartia herdmani*; and a few striking novelties have been described from it of late years, but we have no reason to believe that the number of these is great compared with the number of animals obtained from shallower waters.

Dr. Murray not only insists upon the abundance of animals on the mud, and its importance as the great feeding ground and place of origin of life in the ocean, but he also (p. 1432) draws conclusions as to the relative numbers of animals taken by a single haul of the trawl in deep and shallow waters which can scarcely be received, I think, by marine zoologists without a protest. His statement runs (p. 1432): "It is interesting to compare single hauls made in the deep sea and in shallow water with respect to the number of different species obtained. For instance, at station 146 in the Southern Ocean, at a depth of 1375 fathoms the 200 specimens captured belonged to 59 genera and 78 species." That was with a 10-foot trawl dragged for at most two miles during at most two hours. Murray then goes on to say: "In depths less than 50 fathoms, on the other hand, I cannot find in all my experiments any record of such a variety of organisms in any single haul even when using much larger trawls and dragging over much greater distances." He quotes the statistics of the Scottish Fishery Board's trawlings in the North Sea, with a 25-foot trawl, to show that the average catch is 7·3 species of invertebrata and 8·3 species of fish, the greatest number of both together recorded in one haul being 29 species. Murray's own trawlings in the West of Scotland gave a much greater number of species, sometimes as many as 50, "still not such a great variety of animals as was procured in many instances by the *Challenger's* small trawl in great depths."

Now, in the first place, it is curious that Murray's own table on p. 1437, in which he shows that the "terrigenous" deposits lying along the shore-lines yield many more animals, both specimens and species, per haul, than do the "pelagic" deposits[1] at greater depths, such as red clays and globigerina oozes, seems directly opposed to the conclusion quoted above. In the second place, I am afraid that Dr. Murray has misunderstood the statistics of the Scottish Fishery Board when he quotes them as showing that only 7·3 or so species of invertebrates are brought up, on the average, in the trawl net. I happen to know from Mr. Thomas Scott, F.L.S., the naturalist who has compiled the statistics in question, and also from my own observations when on board the *Garland* on one of her ordinary trawling expeditions, that the invertebrata noted down on the station sheet are merely a few of the more conspicuous or in other ways noteworthy animals. No attempt is made—nor could possibly be made in the time—by the one naturalist who has to attend to tow-nets, water-bottle, the kinds, condition, food, &c., of the fish caught and other matters—to give anything like a complete or even approximate list of the species, still less the number of individuals, brought up in the trawl. I submit, therefore, that it is entirely misleading to compare those Scottish Fishery Board statistics, which were not meant for such a purpose, but only to give a rough idea of the fauna associated with the fish upon certain grounds, with the carefully elaborated results, worked out at leisure by many specialists in their laboratories, of a haul of the *Challenger's* trawl. Of Dr. Murray's own trawlings in the West of Scotland I cannot, of course, speak so positively; but I shall be surprised to learn that the results of each haul were as carefully preserved and as fully worked out by specialists as were the *Challenger* collections.

[1] One of the earliest of the *Challenger* oceanographic results, the classification of the submarine deposits into "terrigenous" and "pelagic," seems inadequate to represent fully the facts in regard to sea-bottoms, so I am proposing elsewhere ("Report of Irish Sea Committee") the following amended classification:—(1) Terrigenous (Murray), where the deposit is formed chiefly of mineral particles derived from the waste of the land; (2) Neritic, where the deposit is chiefly of organic origin, and is derived from the shells and other hard parts of the animals and plants living on the bottom; (3) Planktonic (Murray's "pelagic"), where the greater part of the deposit is formed of the remains of free-swimming animals and plants which lived in the sea over the deposit.

Lastly, on the next Liverpool Marine Biology Committee's dredging expedition in the Irish Sea after the appearance of Dr. Murray's volumes, I set myself to determine the species taken in a haul of the trawl for comparison with the *Challenger* numbers. The haul was taken on June 23, at 7 miles west from Peel, on the north bank, bottom sand and shells, depth 21 fathoms, with a trawl of only 4-foot beam, less than half the size of the *Challenger* one, and it was not down for more than twenty minutes. I noted down the species observed, and I filled two bottles with undetermined stuff which my assistant, Mr. Andrew Scott, and I examined the following day in the laboratory. Our list comes to at least 112 species, belonging to at least 103 genera.[1] I counted 120 duplicate specimens which, added to 112, gives 232 individuals, but there may well have been 100 more. This experience, then, is very different from Murray's, and gives far larger numbers in every respect—specimens, species, and genera—than even the *Challenger* deep-water haul quoted. I append my list of species,[2] and practised marine zoologists will, I think, see at a glance that it is nothing out of the way, that it is a fairly ordinary assemblage of not uncommon animals such as is frequently met with when dredging in the "coralline" zone. I am sure that I have taken better netfuls than this both in the Irish Sea and on the West of Scotland.

In order to get another case on different ground, not of my own choosing, on the first occasion after the publication of Dr. Murray's volumes, when I was out witnessing the trawling observations of the Lancashire Sea Fisheries steamer *John Fell*, I counted, with the help of my assistant, Mr. Andrew Scott, and the men on board, the results of the first haul of the shrimp trawl. It was taken at the mouth of the Mersey estuary, inside the Liverpool bar, on what the naturalist would consider very unfavourable ground, with a bottom of muddy sand, at a depth of 6 fathoms. The shrimp trawl ($1\frac{1}{2}$-inch mesh) was down for one hour, and it brought up over seventeen thousand specimens, referable to at least 39 species,[3] belonging to 34 genera. These numbers have been exceeded on many other hauls taken in the ordinary course of work by the Fisheries steamer in Liverpool Bay—for example, on this occasion the fish numbered 5943, and I have records of hauls on which the fish numbered over 20,000, and the total catch of individual animals must have been nearly 50,000. Can any of Dr. Murray's hauls on the deep mud beat these figures?

The conclusion, then, at which I arrive in regard to the distribution of animals in deep water and in water shallower than 50 fathoms, from my own experience and an examination of the *Challenger* results, is in some respects the reverse of Murray's. I consider that there are more species and more individuals in the shallower waters, that the deep mud as dredged has a poor fauna, that the "Coralline" zone has a much richer one, and that the "Laminarian" zone, where there is vegetable as well as animal food, has probably the richest of all.

In order to come to as correct a conclusion as possible on the matter, I have consulted several other naturalists in regard to the smaller groups of more or less free-swimming Crustacea, such as Copepoda and Ostracoda, which I thought might possibly be in considerable numbers over the mud. I have asked three well-known specialists on such Crustaceans—viz., Prof. G. S. Brady, F.R.S., Mr. Thomas Scott, F.L.S., and Mr. I. C. Thompson, F.L.S.—and they all agree in stating that, although interesting and peculiar, the Copepoda and Ostracoda from the deep mud are not abundant either in species or in individuals.

[1] It is interesting, in connection with Darwin's opinion that an animal's most formidable competitors in the struggle for existence are those of its own kind or closely allied forms, to notice the large proportion of genera to species in such hauls. I have noticed this in many lists, and it certainly suggests that closely related forms are comparatively rarely taken together.

In answer to the question which of the three regions (1) the littoral zone, (2) from low water to 20 fathoms, and (3) from 20 fathoms downwards, is richest in small free-swimming, but bottom-haunting, Crustacea, they all replied the middle region from low water to 20 fathoms, which is the Laminarian zone and the upper edge of the Coralline. Prof. Brady assures me that nearly every other kind of bottom and locality is better than mud for obtaining Ostracoda. Mr. T. Scott considers that Ostracoda are most common in shallow water, from 5 to 20 fathoms. He tells me that, as the result of his experience in Loch Fyne, where a great part of the loch is deep, the richest fauna is always where banks occur, rising up to about 20 fathoms, and having the bottom formed of sand, gravel and shells. The fauna on and over such banks, which are in the Coralline zone, is much richer than on the deeper mud around them. On an ordinary shelving shore on the west coast of Scotland Mr. Scott, who has had great experience in collecting, considers that the richest fauna is usually at about 20 fathoms. My own experience in dredging in Norway is the same. In the centre of the fjords in deep water on the mud there are rare forms, but very few of them, while in shallower water at the sides, above the mud, on gravel, shells, rock, and other bottoms, there is a very abundant fauna.

Probably no group of animals in the sea is of so much importance from the point of view of food as the Copepoda. They form a great part of the food of whales, and of herrings and many other useful fish, both in the adult and in the larval state, as well as of innumerable other animals, large and small. Consequently, I have inquired somewhat carefully into their distribution in the sea, with the assistance of Prof. Brady, Mr. Scott, and Mr. Thompson. These experienced collectors all agree that Copepoda are most abundant, both as to species and individuals, close round the shore, amongst seaweeds, or in shallow water in the Laminarian zone over a weedy bottom. Individuals are sometimes extremely abundant on the surface of the sea amongst the plankton, or in shore pools near high water, where, amongst *Enteromorpha*, they swarm in immense profusion; but, for a gathering rich in individuals, species, and genera, the experienced collector goes to the shallow waters of the Laminarian zone. In regard to the remaining, higher, groups of the Crustacea my friend, Mr. Alfred O. Walker, tells me that he considers them most abundant at depths of 0 to 20 fathoms.

I hope no one will think that these are detailed matters interesting only to the collector, and having no particular bearing upon the great problems of biology. The sea is admittedly the starting point of life on this earth, and the conclusions we come to as to the distribution of life in the different zones must [illegible] modify our views as to the origin of the faunas as to the peopling of the deep sea, the shallow waters, and the land. [illegible] supposes that life started in Pre-Cambrian times on the [illegible], and from there spread upwards into shallower waters, [illegible] to the surface, and, a good deal later, downwards to the [illegible] by means of the cold polar waters. The late Prof. Moseley considered the pelagic, or surface life of the ocean [illegible] the primitive life from which all the others have been derived. Prof. W. K. Brooks ("The Genus Salpa," 1893, p. 156, [illegible]) [illegible] that there was a primitive pelagic fauna, consisting of [illegible] microscopic plants and animals, and "that pelagic life was [illegible] for a long period during which the bottom was uninhabited."

I, on the other hand, for the reasons given fully above, consider that the Laminarian zone close to low-water mark is at [illegible] life, that it probably has been so in the [illegible], [illegible] to express a more definite opinion as to [illegible] Pre-Cambrian times, life in its simplest forms first [illegible] I [illegible] reason why any other zone should be con[illegible] better claim than what is now the Laminarian [illegible]. It is there, at present at any rate, in the [illegible] Laminarian zone, at the point of junction of [illegible], where there is a profusion of food, where the [illegible] stretches or worn away from the land [illegible], where the animals are able to receive the [illegible] light and heat, oxygen and food, without [illegible] to the air, rain, frost, sun, and other [illegible] the littoral zone, it is there that life [illegible] most active, competition [illegible] that the surrounding con[illegible] animal life; and, therefore, it [illegible] that, as the result of over[illegible] downward to the abysses, [illegible] to the shore. Finally, it is in this Laminarian zone, probably, that under the stress of competition between individuals and between allied species evolution of new forms by means of natural selection has been most active. Here, at any rate, we find, along with some of the most primitive of animals, some of the most remarkably modified forms, and some of the most curious cases of minute adaptation to environment. This brings us to the subject of

BIONOMICS,

which deals with the habits and variations of animals, their modifications, and the relations of these modifications to the surrounding conditions of existence.

It is remarkable that the great impetus given by Darwin's work to biological investigation has been chiefly directed to problems of structure and development, and not so much to bionomics until lately. Variations amongst animals in a state of nature is, however, at last beginning to receive the attention it deserves. Bateson has collected together, and classified in a most useful book of reference, the numerous scattered observations on variation made by many investigators, and has drawn from some of these cases a conclusion in regard to the discontinuity of variation which many field zoologists find it hard to accept.

Weldon and Karl Pearson have recently applied the methods of statistics and mathematics to the study of individual variation. This method of investigation, in Prof. Weldon's hands, may be expected to yield results of great interest in regard to the influence of variations in the young animal upon the chance of survival, and so upon the adult characteristics of the species. But while acknowledging the value of these methods, and admiring the skill and care with which they have been devised and applied, I must emphatically protest against the idea which has been suggested, that only by such mathematical and statistical methods of study can we successfully determine the influence of the environment on species, gauge the utility of specific characters, and throw further light upon the origin of species. For my part, I believe we shall gain a truer insight into those mysteries which still involve variations and species by a study of the characteristic features of individuals, varieties, and species in a living state in relation to their environment and habits. The mode of work of the old field naturalists, supplemented by the apparatus and methods of the modern laboratory, is, I believe, not only one of the most fascinating, but also one of the most profitable fields of investigation for the philosophical zoologist. Such studies must be made in that modern outcome of the growing needs of our science, the Zoological Station, where marine animals can be kept in captivity under natural conditions, so that their habits may be closely observed, and where we can follow out the old precept—first, observation and reflection; then experiment.

The biological stations of the present day represent, then, a happy union of the field work of the older naturalists with the laboratory work of the comparative anatomist, histologist, and embryologist. They are the culmination of the "Aquarium" studies of Kingsley and Gosse, and of the feeling in both scientific men and amateurs, which was expressed by Herbert Spencer when he said: "Whoever at the seaside has not had a microscope and an aquarium has yet to learn what the highest pleasures of the seaside are." Moreover, I feel that the biological station has come to the rescue, at a critical moment, of our laboratory worker who, without its healthy, refreshing influence, is often in these latter days in peril of losing his intellectual life in the weary maze of microtome methods and transcendental cytology. The old Greek myth of the Libyan giant, Antæus, who wrestled with Hercules and regained his strength each time he touched his mother earth, is true at least of the zoologist. I am sure he derives fresh vigour from every direct contact with living nature.

In our tanks and artificial pools we can reproduce the Littoral and the Laminarian zones; we can see the methods of feeding and breeding—the two most powerful factors in influencing an animal. We can study mimicry, and test theories of protective and warning colouration.

The explanations given by these theories of the varied forms and colours of animals were first applied by such leaders in our science as Bates, Wallace, and Darwin, chiefly to insects and birds, but have lately been extended, by the investigations of Giard, Garstang, Clubb, and others, to the case of marine animals. I may mention very briefly one or two examples. Amongst the Nudibranchiate Mollusca—familiar animals around

most parts of our British coasts—we meet with various forms which are edible, and, so far as we know, unprotected by any defensive or offensive apparatus. Such forms are usually shaped or coloured so as to resemble more or less their surroundings, and so become inconspicuous in their natural haunts. *Dendronotus arborescens*, one of the largest and most handsome of our British Nudibranchs, is such a case. The large, branched processes on its back, and its rich purple-brown and yellow markings, tone in so well with the masses of brown and yellow zoophytes and purplish-red seaweeds, amongst which we usually find *Dendronotus*, that it becomes very completely protected from observation; and, as I know from my own experience, the practised eye of the naturalist may fail to detect it lying before him in the tangled forests of a shore-pool.

Other Nudibranchs, however, belonging to the genus *Eolis* for example, are coloured in such a brilliant and seemingly crude manner, that they do not tone in with any natural surroundings, and so are always conspicuous. They are active in their habits, and seem rather to court observation than to shun it. When we remember that such species of *Eolis* are protected by the numerous stinging cells in the cnidophorous sacs placed on the tips of all the dorsal processes, and that they do not seem to be eaten by other animals, we have at once an explanation of their fearless habits and of their conspicuous appearance. The brilliant colours are in this case of a warning nature, for the purpose of rendering the animal provided with the stinging cells noticeable and recognisable. But it must be remembered that in a museum jar, or in a laboratory dish, or as an illustration in a book or on the wall, *Dendronotus* is quite as conspicuous and striking an animal as *Eolis*. In order to interpret correctly the effect of their forms and colours, we must see them alive and at home, and we must experiment upon their edibility or otherwise in the tanks of our biological stations.[1]

Let me give you one more example of a somewhat different kind. The soft, unprotected mollusc, *Lamellaria perspicua*, is not uncommonly found associated (as Giard first pointed out) with colonies of the compound Ascidian *Leptoclinum maculatum*, and in these cases the *Lamellaria* is found to be eating the *Leptoclinum*, and lies in a slight cavity which it has excavated in the Ascidian colony, so as to be about flush with the general surface. The integument of the mollusc is, both in general tint and also in surface markings, very like the Ascidian colony with its scattered ascidiozooids. This is clearly a good case of protective colouring. Presumably the *Lamellaria* escapes the observation of its enemies through being mistaken for a part of the *Leptoclinum* colony; and the *Leptoclinum*, being crowded like a sponge with minute sharp-pointed spicules, is, I suppose, avoided as inedible by carnivorous animals, which might devour such things as the soft unprotected mollusc. But the presence of the spicules evidently does not protect the *Leptoclinum* from *Lamellaria*, so that we have, if the above interpretation is correct, the curious result that the *Lamellaria* profits by a protective characteristic of the *Leptoclinum*, for which it has itself no respect, or, to put it another way, the *Leptoclinum* is protected against enemies to some extent for the benefit of the *Lamellaria*, which preys upon its vitals.

It is, to my mind, no sufficient objection to theories of protective and warning colouration that careful investigation may from time to time reveal cases where a disguise is penetrated, a protection frustrated, an offensive device supposed to confer inedibility apparently ignored. We must bear in mind that the enemies, as well as their prey, are exposed to competition, are subject to natural selection, are undergoing evolution; that the pursuers and the pursued, the eaters and the eaten, have been evolved together; and that it may be of great advantage to be protected from *some*, even if not from all enemies. Just as on land, some animals can browse upon thistles whose "nemo me impune lacessit" spines are supposed to confer immunity from attack, so it is quite in accord with our ideas of evolution by means of natural selection to suppose that some marine animals have evolved an indifference to the noxious sponge or to the bristling Ascidian, which are able, by their defensive characteristics, like the thistle, to repel the majority of invaders.

Although we can keep and study the Littoral and Laminarian animals at ease in our zoological stations, it may perhaps be questioned how far we can reproduce in our experimental and observational tanks the conditions of the "Coralline" and the "Deep-mud" zones. One might suppose that the pressure —which we have no means as yet for supplying[1]—and which at 30 fathoms amounts to nearly 100 lbs. on the square inch, and at 80 fathoms to about 240 lbs., or over 2 cwt. on the square inch, would be an essential factor in the life conditions of the inhabitants of such depths, and yet we have kept half a dozen specimens of *Calocaris macandreæ*, dredged from 70 to 80 fathoms, alive at the Port Erin Biological Station for several weeks; we have had both the red and the yellow forms of *Sarcodictyon catenata*, dredged from 30 to 40 fathoms, in a healthy condition with the polypes freely expanded for an indefinite period; and Mr. Arnold Watson has kept the Polynoid worm, *Panthalis oerstedi*, from the deep mud at over 50 fathoms, alive, healthy, and building its tube under observation, first for a week at the Port Erin Station, and then for many months at Sheffield in a comparatively small tank with no depth of water. Consequently it seems clear that, with ordinary care, almost any marine animals from such depths as are found within the British area may be kept under observation and submitted to experiment in healthy and fairly natural conditions. The Biological Station, with its tanks, is in fact an arrangement whereby we bring a portion of the sea with its rocks and bottom deposits and seaweeds, with its inhabitants and their associates, their food and their enemies, and place it for continuous study on our laboratory table. It enables us to carry on the bionomical investigations to which we look for information as to the methods and progress of evolution; in it lie centred our hopes of a comparative physiology of the invertebrates—a physiology not wholly medical —and finally to the Biological Station we confidently look for help in connection with our coast fisheries. This brings me to the last subject which I shall touch upon, a subject closely related both to Oceanography and Bionomics, and one which depends much for its future advance upon our Biological Stations—that is the subject of

Aquiculture,

or industrial Ichthyology, the scientific treatment of fishery investigations, a subject to which Prof. M'Intosh has first in this country directed the attention of zoologists, and in which he has been guiding us for the last decade by his admirable researches. What chemistry is to the aniline, the alkali, and some other manufactures, marine zoology is to our fishing industries.

Although zoology has never appealed to popular estimation as a directly useful science having industrial applications in the same way that Chemistry and Physics have done, and consequently has never had its claims as a subject of technical education sufficiently recognised; still, as we in this Section are well aware, our subject has many technical applications to the arts and industries. Biological principles dominate medicine and surgery. Bacteriology, brewing, and many allied subjects are based upon the study of microscopic organisms. Economic entomology is making its value felt in agriculture. Along all these and other lines there is a great future opening up before biology, a future of extended usefulness, of popular appreciation, and of value to the nation—and not the least important of these technical applications will, I am convinced, be that of zoology to our fishing industries. When we consider their enormous annual value about eight millions sterling at first hand to the fisherman, and a great deal more than that by the time the products reach the British public, when we remember the very large proportion of our population who make their living directly or indirectly (as boatbuilders, net-makers, &c.) from the fisheries, and the still larger proportion who depend for an important element in their food supply upon these industries; when we think of what we pay other countries France, Holland, Norway —for oysters, mussels, lobsters, &c., which we could rear in this country if our sea-shores and our sea-bottom were properly cultivated; and when we remember that fishery cultivation or aquiculture is applied zoology, we can readily realise the enormous value to the nation which this direct application of our science will one day have -perhaps I ought rather to say, we can *scarcely* realise the extent to which zoology may be made the guiding science of a great national industry. The flourishing shellfish industries of France, the oyster culture at Arcachon and Marennes, and the mussel culture by bouchots in the Bay of Aiguillon, show what can be done as the result of encouragement and wise assistance from Government, with constant

[1] See my experiments on Fishes with Nudibranchs, in *Trans. Biol. Soc.*, Liverpool, vol. iv. p. 151; and NATURE for June 26, 1890.

[1] Following up M. Regnard's experiments, some mechanical arrangement whereby water could be kept circulating and aerated under pressure in closed tanks might be devised, and ought to be tried at some zoological station. I learn from the Director at the Plymouth Station that some of the animals from deep water, such as Polyzoa, do not expand in their tanks.

industry on the part of the people, directed by scientific knowledge. In another direction the successful hatching of large numbers (hundreds of million) of cod and plaice by Captain Dannevig in Norway, and by the Scottish Fishery Board at Dunbar, opens up possibilities of immense practical value in the way of restocking our exhausted bays and fishing banks—depleted by the over-trawling of the last few decades.

The demand for the produce of our seas is very great, and would probably pay well for an increased supply. Our choicer fish and shellfish are becoming rarer, and the market prices are rising. The great majority of our oysters are imported from France, Holland, and America. Even in mussels we are far from being able to meet the demand. In Scotland alone the long line fishermen use nearly a hundred millions of mussels to bait their hooks every time the lines are set, and they have to import annually many tons of these mussels at a cost of from £3 to £3 10s. a ton. . . .

Whether the wholesale introduction of the French method of mussel culture, by means of bouchots, on to our shores would be a financial success is doubtful. Material and labour are dearer here, and beds, scars, or scalps seem, on the whole, better fitted to our local conditions; but as innumerable young mussels all round our coast perish miserably every year for want of suitable objects to attach to, there can be no reasonable doubt that the judicious erection of simple stakes or plain bouchots would serve a useful purpose, at any rate in the collection of seed, even if the further rearing be carried on by means of the bed system.

All such aquicultural processes require, however, in addition to the scientific knowledge, sufficient capital. They cannot be successfully carried out on a small scale. When the zoologist has once shown as a laboratory experiment, in the zoological station, that a particular thing can be done—that this fish can be hatched or that shellfish reared under certain conditions which promise to be an industrial success, then the matter should be carried out by the Government[1] or by capitalists on a sufficiently large scale to remove the risk of results being vitiated by temporary accident or local variation in the conditions. It is contrary, however, to our English traditions for Government to help in such a matter, and if our local Sea Fisheries Committees have not the necessary powers nor the available funds, there remains a splendid opportunity for opulent landowners to erect sea-fish hatcheries on the shores of their estates, and for the rich merchants of our great cities to establish aquiculture in their neighbouring estuaries, and by so doing, instruct the fishing population, resuscitate the declining industries, and cultivate the barren shores—in all reasonable probability to their own ultimate profit.

In addition to the farming of our shores there is a great deal to be done in promoting the fishing industries on the inshore and offshore grounds along our coast, and in connection with such work the first necessity is a thorough scientific exploration of our British seas by means of a completely fitted dredging and trawling expedition. Such exploration can only be done in little bits, spasmodically, by private enterprise. From the time of Edward Forbes it has been the delight of British marine zoologists to explore, by means of dredging from yachts or hired vessels during their holidays, whatever areas of the neighbouring seas were open to them. Some of the greatest names in the roll of our zoologists, and some of the most creditable work in British zoology, will always be associated with dredging expeditions. Forbes, Wyville Thomson, Carpenter, Gwyn Jeffreys, M'Intosh, and Norman—one can scarcely think of them without recalling—

> Hurrah for the dredge, with its iron edge,
> And its mystical triangle,
> And its hided net, with meshes set,
> Odd fishes to entangle![2]

Much good pioneer work in exploration has been done in the past by these and other naturalists, and much is now being done locally by committees or associations—by the Dublin Royal Society on the West of Ireland, by the Marine Biological Association at Plymouth, by the Fishery Board in Scotland, and by the Liverpool Marine Biology Committee in the Irish Sea; but few zoologists or zoological committees have the means, the opportunity, the time to devote, along with their professional duties, to the thorough systematic survey of our whole British sea-area which is really required. Those who have not had experience of it can scarcely realise how much time, energy, and money it requires to keep up a series of dredging expeditions, how many delays, disappointments, expensive accidents and real hardships there are, and how often the naturalist is tempted to leave unprofitable ground, which ought to be carefully worked over, for some more favoured spot where he knows he can count upon good spoil. And yet it is very necessary that the whole ground—good or bad though it may be from the zoological point of view—should be thoroughly surveyed, physically and biologically, in order that we may know the conditions of existence which environ our fishes, on their feeding grounds, their spawning grounds, their "nurseries," or wherever they may be.

The British Government has done a noble piece of work which will redound to its everlasting credit in providing for, and carrying out, the *Challenger* expedition. Now that that great enterprise is completed, and that the whole scientific world is united in appreciation of the results obtained, it would be a glorious consequence, and surely a very wise action in the interests of the national fisheries, for the Government to fit out an expedition, in charge of two or three zoologists and fisheries experts, to spend a couple of years in exploring more systematically than has yet been done, or can otherwise be done, our British coasts from the Laminarian zone down to the deep mud. No one could be better fitted to organise and direct such an expedition than Dr. John Murray.

Such a detailed survey of the bottom and the surface waters, of their conditions and their contents, at all times of the year for a couple of years, would give us the kind of information we require for the solution of some of the more difficult fishery problems—such as the extent and causes of the wanderings of our fishes, which "nurseries" are supplied by particular spawning grounds, the reason of the sudden disappearance of a fish such as the haddock from a locality, and in general the history of our food fishes throughout the year. It is creditable to our Government to have done the pioneer work in exploring the great ocean, but surely it would be at least equally creditable to them—and perhaps more directly and immediately profitable, if they look for some such return from scientific work—to explore our own seas and our own sea-fisheries.

There is still another subject connected with the fisheries which the the biologist can do much to elucidate—I mean the diseases of edible animals and the effect upon man of the various diseased conditions. It is well known that the consumption of mussels taken from stagnant or impure water is sometimes followed by severe symptoms of irritant poisoning which may result in rapid death. This "musselling" is due to the presence of an organic alkaloid or ptomaine, in the liver of the mollusc, formed doubtless by a micro-organism in the impure water. It is clearly of the greatest importance to determine accurately under what conditions the mussel can become infected by the micro-organism, in what stage it is injurious to man, and whether, as is supposed, steeping in pure water with or without the addition of carbonate of soda will render poisonous mussels fit for food.

During this last year there has been an outcry, almost amounting to a scare, and seriously affecting the market,[1] as to the supposed connection between oysters taken from contaminated water and typhoid fever. This, like the musselling, is clearly a case for scientific investigation, and, with my colleague, Prof. Boyce, I have commenced a series of experiments and observations, partly at the Port Erin Biological Station, where we have oysters laid down on different parts of the shore under very different conditions, as well as in dishes and tanks, and partly at University College, Liverpool.

Our object is to determine the effect of various conditions of water and bottom upon the life and health of the oyster, the effect of the addition of various impurities to the water, the conditions under which the oyster becomes infected with the typhoid bacillus, and the resulting effect upon the oyster, the period during which the oyster remains infectious, and lastly, whether any simple practicable measures can be taken (1) to determine whether an oyster is infected with typhoid, and (2) to render such an oyster innocuous to man. As Prof. Boyce and I propose to lay a paper upon this subject before the Section, I shall not occupy further time now by a statement of our methods and results.

I have probably already sufficiently indicated to you the extent and importance of the applications of our science to

[1] We [illegible] Fisheries Central Board or Government Department of Fisheries [illegible] experts, and that not merely for the [illegible] but still more, in order that [illegible] aquicultural experiments [illegible].

[1] I am told that between December and March the oyster trade decreased 70 per cent.

practical questions connected with our fishing industries. But if the zoologist has great opportunities for usefulness, he ought always to bear in mind that he has also grave responsibilities in connection with fisheries investigations. Much depends upon the results of his work. Private enterprise, public opinion, local regulations, and even imperial legislation, may all be affected by his decisions. He ought not lightly to come to conclusions upon weighty matters. I am convinced that of all the varied lines of research in modern zoology, none contains problems more interesting and intricate than those of bionomics, oceanography, and the fisheries, and of these three series the problems connected with our fisheries are certainly not the least interesting, not the least intricate, and not the least important in their bearing upon the welfare of mankind.

APPENDIX.

List of Species taken in one haul, on June 23, 1895 (see p. 497).

SPONGES:

Reniera, sp.
Halichondria, sp.
Cliona celata
Suberites domuncula
Chalina oculata

COELENTERATA:

Dicoryne conferta
Halecium halecinum
Sertularia abietina
Coppinia arcta
Hydrallmania falcata
Campanularia verticillata
Lafoea dumosa
Antennularia ramosa
Alcyonium digitatum
Virgularia mirabilis
Sarcodictyon catenata
Sagartia, sp.
Adamsia palliata

ECHINODERMATA:

Cucumaria, sp.
Thyone fusus
Asterias rubens
Solaster papposus
Stichaster roseus
Porania pulvillus
Palmipes placenta
Ophiocoma nigra
Ophiothrix fragilis
Amphiura chiajii
Ophioglypha ciliata
O. albida
Echinus sphæra
Spatangus purpureus
Echinocardium cordatum
Brissopsis lyrifera
Echinocyamus pusillus

VERMES:

Nemertes neesii
Chætopterus, sp.
Spirorbis, sp.
Serpula, sp.
Sabella, sp.
Owenia filiformis
Aphrodite aculeata
Polynoe, sp.

CRUSTACEA:

Scalpellum vulgare
Balanus, sp.
Cyclopicera nigripes
Acontiophorus elongatus
Artotrogus magniceps
Dyspontius striatus
Zaus goodsiri
Laophonte thoracica
Stenhelia reflexa
Lichomolgus forficula
Anonyx, sp.
Galathea intermedia
Munida bamffica
Crangon spinosus
Stenorhynchus rostratus
Inachus dorsettensis
Hyas coarctatus
Xantho tuberculatus
Portunus pusillus
Eupagurus bernhardus
E. prideauxii
E. cuanensis
Eurynome aspera
Ebalia tuberosa

POLYZOA:

Pedicellina cernua
Tubulipora, sp.
Crisia cornuta
Cellepora pumicosa, and three or four undetermined species of Lepralids
Flustra securifrons
Scrupocellaria reptans
Cellularia fistulosa

MOLLUSCA:

Anomia ephippium
Ostrea edulis
Pecten maximus
P. opercularis
P. tigrinus
P. pusio
Mytilus modiolus
Nucula nucleus
Cardium echinatum
Lissocardium norvegicum
Cyprina islandica
Solen pellucidus
Venus gallina
Lyonsia norvegica
Scrobicularia prismatica
Astarte sulcata
Modiolaria marmorata
Saxicava rugosa
Chiton, sp.
Dentalium entale
Emarginula fissura
Velutina lævigata
Turritella terebra
Natica alderi
Fusus antiquus
Aporrhais pespelicani
Oscanius membranaceus
Doris, sp.
Eolis coronata
Tritonia plebeia

TUNICATA:

Ascidiella virginea
Styelopsis grossularia
Eugyra glutinans
Botryllus, sp.
B., sp.

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY L. F. VERNON-HARCOURT, M.A., M.INST.C.E.

The Relation of Engineering to Science.

THE selection of a subject for an inaugural address, necessitated by the honour conferred upon me of presiding over this Section, has been rendered peculiarly difficult, both on account of the numerous able addresses delivered in past years by my eminent predecessors in this office, and also by the circumstance that the branches of engineering to which most of my professional life has been devoted have not as intimate a connection with mechanical science as some others. Moreover, whilst former Presidents of Section G have frequently dealt, in their addresses, with the progress of those special branches of engineering in which they have had most practical experience, such a course, in the present instance, would have exposed me to the danger of merely repeating information and reiterating opinions already recorded in the *Proceedings* of the Institution of Civil Engineers, and in other publications, with reference to maritime and hydraulic engineering. It has, accordingly, appeared to me that the exceptional occasion of addressing a gathering of scientific persons, and of engineers who testify their interest in science by attending these meetings, would be best utilised by considering the relation that engineering in general, and maritime and hydraulic engineering in particular, bear to pure science, and the means by which progress in engineering science might be best promoted, and its scope and utility increased.

In addition to the oft-quoted definition of civil engineering as "the art of directing the great sources of power in nature for the use and convenience of man," Thomas Tredgold also defined it, in 1828, as "that practical application of the most important principles of natural philosophy which has, in a considerable degree, realised the anticipations of Bacon and changed the aspect and state of affairs in the whole world." If the influence of engineering could be thus described in 1828, when railways and steamships were in their infancy and the electric telegraph and the various modern applications of electricity and magnetism had not come into existence, how far more true is it at the present day, when the various branches of engineering have attained such a marvellous development! Tredgold also realised, at that early date, that the resources of the engineer must be further directed so as to cope with the injurious forces of nature, such as floods, storms, and unsanitary conditions, and thus protect men from harm as well as promote their well-being. Moreover, he foresaw the great capabilities of development possessed by engineering, and its dependence on science: for he stated that "the real extent to which civil engineering may be applied is limited only by the progress of science; its scope and utility will be increased with every discovery in philosophy, and its resources with every invention in mechanical or chemical art, since its bounds are unlimited, and equally so must be the researches of its professors." If the full significance of these statements may be accepted as correct, engineers might fairly claim to have a right to say, "As engineers we are necessarily men of science, and no branch of science is outside our province." It might, however, be said that no engineer, with his absorbing professional avocations, would have the time to acquire even the rudiments of the principal branches of science, with their ever-increasing developments, to the study of each of which the life-work of many earnest searchers into the secrets of nature is wholly devoted. Nevertheless, a few branches of science, such as physiology, biology, and botany, appear to be beyond the scope of practical engineering; whilst a moderate acquaintance with some others might suffice for the needs of the engineer, except in certain special branches, supplemented, as it can readily be, by the advice of a specialist in complicated cases.

Among the branches of science necessary for the engineer, two may be regarded as of the highest importance, namely, mathematics and physics, upon which the science of engineering mainly depends; and without an adequate knowledge of these, no person should be able at the present day to enter the profession of a civil engineer. Other sciences of considerable, though of comparatively minor, importance to engineers in general, are chemistry, geology, and meteorology; but each of these assumes an enhanced value in special branches of engineering.

Mathematics in Relation to Engineering.—The pre-eminent importance of mathematics in relation to engineering may be regarded as fully established; and a President of the Institution of Civil Engineers would not now tell a pupil, at their first interview, that he had done very well without mathematics, a remark made to me by a justly celebrated engineer over thirty years ago.

Surveying, which is the handmaid of civil engineering, depends upon the principles of geometry for its accuracy; and ordinary triangulation, geodesy, and the rapid method of surveying and taking levels in rough country, known as tacheometry, are based on trigonometry and aided by logarithms. Tacheometry, indeed, though carried out by means of a specially constructed theodolite, may be regarded as the practical application of the familiar problem in trigonometry of finding the height and distance of an inaccessible tower. A proposition of Euclid forms the basis of the simplest and speediest method of setting out circular curves for railways; whilst astronomy has been resorted to for facilitating surveying in unexplored regions. The laws of statics are involved in the design of bridges, especially those of large span, and also of masonry dams, roofs, floors, columns, and other structures; whilst torsion, internal ballistics, the trajectory of a projectile, the forces of impact, and the stoppage of a railway train are dynamical problems. Hydrostatics and hydrodynamics provide the foundation of hydraulic engineering; though, owing to the complicated nature of the flow of water, observations and experiments have been necessary for obtaining correct formulæ of discharge. Geometrical optics has been employed for determining the forms of the lenses for giving a parallel direction to the rays proceeding from the lamps of a lighthouse, in accordance with the principles laid down by Fresnel. The theory of the tides, the tide tables giving the predicted tidal rise at the principal ports, and wave motion—questions of considerable importance to the harbour engineer—depend upon mathematical and astronomical calculations; whilst the stability and rolling of ships, the lines for a vessel of least resistance in passing through water, and the dimensions and form of screw propellers, to obtain the greatest speed with a given expenditure of power, have been determined by mathematical considerations aided by experiment. Electrical engineering depends very largely upon mathematical and physical problems, guided by the results of practical experience; and the possibility of the commercial success of the first Atlantic cable, depending upon the rate of transmission of the signals and the loss of electrical intensity in that long journey, has been shown by Dr. John Hopkinson in his "James Forrest" lecture, to have been determined by Lord Kelvin by the solution of a partial differential equation (*Proceedings Inst. C.E.* vol. cxviii. p. 330).

All branches of applied mathematics have, accordingly, been utilised by engineers, or, as in the case of several general principles and tidal calculations, by mathematicians to their benefit; but graphic statics will probably gradually supersede analytical methods for the calculation of stresses, as more rapid in operation, and less subject to errors, which are also more easily detected in graphic diagrams. Pure mathematics, in its higher branches, appears to have a less direct connection with engineering; but applied mathematics is so largely dependent upon pure mathematics, that the latter, including the calculus and differential equations, cannot be safely neglected by the engineer, though certain branches, as, for instance, probabilities, the theory of numbers, the tracing of curves, and some of the more abstruse portions of the subject, may be dispensed with.

Physics in Relation to Engineering.—Physics has been placed after mathematics, as many physical problems are determined by mathematics; but in several respects physics, with its very wide scope in its relation to the various properties of matter, is of equal importance to engineers, for there are few [illegible] engineering in which no part is borne by physical considerations.

The surveyor avails himself of physics when heights are [illegible] barometer, or by the temperature at which water [illegible]; and the spirit-level is a physical instrument adapted [illegible] for levelling across land. Evaporation, con[illegible] heat are of great importance in regard to [illegible]; and the expansive force of the [illegible], the diminution of friction, and the [illegible] are essential elements in the [illegible] engines. Allowance for expansion [illegible] has to be made in all large [illegible] to changes in temperature have to be taken into account. The temperature, also, which decreases with the elevation above the sea-level, and the distance from the equator, limits the height to which railways can be carried without danger of blocking by snow; whilst the temperature, by increasing about 1° F. with every 60 feet below the surface of the earth, limits the depth at which tunnels can be driven under high mountain ranges. Congelation of the soil is employed, as will be explained by M. Gobert, in excavations through water-bearing strata.

Compressed air is used by engineers for excluding the water from subaqueous foundations, so that excavations can be made and foundations laid, at considerable depths below the water-level, with the same certainty as on dry land. The compression of air, and its subsequent absorption of heat on being liberated and expanding in a chamber, are employed for refrigerating the chambers in which meat and other perishable supplies are preserved. Compressed air is employed for working the boring machinery in driving long tunnels through rock, and provides, at the same time, means of ventilation; and it also serves to convey parcels along pneumatic underground tubes. Moreover, the compressed-air and vacuum brakes are the most efficient systems of automatic and continuous brakes, which have done so much to promote safety in railway travelling, and in reducing the loss of time in the pulling up of frequently stopping trains. The production of a more perfect vacuum than can be produced by the ordinary air-pump, might have been supposed to be merely an interesting physical result (*Journal* of the Chemical Society, June 1864); but, in fact, the preservation of the heated filament of carbon in the incandescent electric light has been rendered possible only by the far more perfect vacuum obtained by the Sprengel vacuum pump, by which the air is exhausted down to so low a pressure as a two-hundred millionth of an atmosphere.

The illuminating power of different sources of light is of great importance in determining the distance at which the concentrated rays from a lighthouse can be rendered visible, as well as in relation to the lighting of streets and houses; and the refrangibility of the rays emitted, or the nature of their spectrum, should not be disregarded, as upon this depends the power of a light to penetrate mist and fog, which cut off the rays at the violet end of the spectrum, and have comparatively little influence on the least refrangible red rays (*Proceedings* Inst. C.E., vol. lvii. pp. 145–148). The effect also of the colouring of lights on their visibility is of interest in determining the shades of colour to be used for signals and ship-lights, and also the relative power of the lights required for different colours to secure equal illuminating power. Distinctions of colour are essential in these cases; but for distinguishing lighthouses, the use of coloured glasses has been abandoned, on account of their impairing the light emitted; and the desired indication has been effected by varying the number and duration of the flashes and eclipses in each lighthouse. The detection of colour-blindness is of interest to engineers, as this physical infirmity incapacitates men from acting as engine-drivers, signalmen, or navigating seamen. The use of compressed oil gas enables buoys and beacons to give a warning or guiding light for about three months without requiring attention; and the electric light has accelerated the passage through the Suez Canal from 30½ hours to 20 hours, and has greatly increased the capacity of the canal for traffic by enabling navigation to be carried on at night. The electric light also affords an excellent, safe, and cool light in the confined cabins on board ship, in the headings of long tunnels, and in the working-chambers filled with compressed air used for sinking subaqueous foundations.

Acoustics might seem to have little relation to engineering; but the soundness of the wheels of a train are tested by the noise they give when struck with a hammer; warning notes are emitted by railway and steamship whistles, the foghorn on board ship, and the whistling and bell-buoys employed for marking shoals or the navigable channel; whilst the striking of bells, the blast of steam sirens, and the explosion of compressed gun-cotton cartridges and rockets indicate the position of lighthouses in foggy weather. The most powerful sounds that can be produced by the help of steam appear to have a very limited range as compared with light; for, under ordinary conditions, the most powerful siren ceases to be audible at a distance of six or seven miles; whilst the transmission of sound is very much affected by the wind and the condition of the atmosphere. It seems possible that loud detonations at short intervals may be more readily heard than the continuous blast of a steam trumpet.

Electrical engineering is very intimately connected with physics, for it really is the application of electricity to industrial purposes. The very close relation between electricity and magnetism, discovered by Oersted in 1820, and further established by the remarkable researches of Faraday, has led to the present system of generating electricity by the relative movement of coiled conductors and electro-magnets, in dynamo-electric machines worked by a steam-engine or other motive power. The electrical current thus generated can be transmitted to a distance with little loss of energy; and it can either be used directly for lighting by arc or incandescent lamps, or be reconverted into mechanical power by the intervention of another dynamo. Electricity is also employed for the simultaneous firing of a series of mines, at a safe distance from the site of the explosion.

The convertibility of heat and energy, indicated by Mayer, forms the basis of thermodynamics; and the mechanical equivalent of heat, a physical problem of the highest interest, determined by Joule in 1843, furnishes a measure of the amount of work that can be possibly obtained by a given expenditure of heat in heat-engines.
